PENETRATING PROLONGED ACTION

PONTOCAINE HYDROCHLORIDE in OPHTHALMOLOGY and RHINOLARYNGOLOGY

Dependable anesthesia of the mucous membranes is readily obtained by the topical application of Pontocaine Hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and non-operative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of $\frac{1}{2}$ oz. and 2 oz.
For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

Penicillin

FOR THE EYES

Simple effective chemotherapy

The benefits derived from the local ophthalmic use of penicillin can be obtained conveniently by means of a suitable ointment.

Like the active drug itself Penicillin Eye Ointment is effective against a variety of organisms. Thus, satisfactory results have been observed in blepharitis, acute and chronic conjunctivitis, gonorrheal ophthalmia, trachoma, infections and ulcerations of the cornea, and prophylactically following corneal injury.

HOW SUPPLIED

Penicillin Eye Ointment—Winthrop, 500 units per Gram and 1000 units per Gram, in $\frac{1}{8}$ oz. tubes.

PENETRATING PROLONGED ACTION

PONTOCAINE HYDROCHLORIDE in OPHTHALMOLOGY and RHINOLARYNGOLOGY

Dependable anesthesia of the mucous membranes is readily obtained by the topical application of Pontocaine Hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and non-operative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of $\frac{1}{4}$ oz. and 2 oz.
For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

PERSISTENCE AND HYPERPLASIA OF THE
PRIMARY VITREOUS

(TUNICA VASCULOSA LENTIS OR RETROLENTAL FIBROPLASIA)

ALGERNON B. REESE, M.D., AND FRANK PAYNE, M.D.
New York

This condition, which usually manifests itself as a bilateral congenital lesion of premature infants, has always appeared sporadically, but of late there has been an increased incidence, probably stemming from a lower mortality of premature babies. In the past decade or more, a number of measures adopted by the pediatricians have contrived to save the lives of many premature babies formerly lost. This seems to be an important reason why the lesion under discussion is encountered more frequently now.

We wish to report on 50 cases which, we believe, belong to this group, and the following table shows that the incidence of our cases has been higher during the past decade.

The first reference we can find to this condition dates back to 1851 (Howard¹) and since then many articles have appeared describing various clinical and pathologic aspects of the lesion under various synonyms some of which are as follows: persistent thickened hyaloid artery with secondary changes (Nettleship,² 1873), persistent hyaloid canal and artery (Gardiner,³ 1880), persistence and

thickening of the posterior fibrovascular sheath of the lens (Collins,⁴ 1892; Pollock,⁵ 1923), atypical development of the anterior part of the vitreous with or without a persistent hyaloid artery (Collins,⁴

1892), congenital membrane behind the lens (Parsons,⁶ 1902), persistence of remains of the tunica vasculosa lentis (Bruckner,⁷ 1907), persistent posterior fibrovascular sheath of the lens (Lane,⁸ 1919), persistence of embryonic fibrovascular sheath of the crystalline lens (Lent and Lyon,⁹ 1922), remains of the tunica vasculosa lentis (Gifford and Latta,¹⁰ 1923; Lloyd,¹¹ 1931), pseudophakia fibrosa of Czermak (Fuchs,¹²

*From the Institute of Ophthalmology of the Presbyterian Hospital. Read in part at the eighty-first annual meeting of the American Ophthalmological Society, at Hot Springs, Va., November, 1945.

1923), opaque membrane behind the lens (Collins and Mayou,¹³ 1925), shrunken fibrous tissue cataract (Collins and Mayou,¹⁴ 1925), posterior lenticonus (Collins and Mayou,¹⁵ 1925), congenital connective tissue formation in the vitreous chamber (Collins and Mayou,¹⁶ 1925), posterior polar cataract (Mann,¹⁷ 1937), fibrous tissue cataract (Mann,¹⁸ 1937), persistence of the vascular sheath of the lens (Duke-Elder,¹⁹ 1938), fibroblastic overgrowth of persistent tunica vasculosa lentis (Terry,²⁰ 1942), and retrolental fibroplasia (Terry,²¹ 1942). We believe that all of these references refer to various manifestations of the same basic lesion. Terry, in a series of papers²⁰⁻²⁴ in which he gave the results of his most thorough study of this subject, chose the term "retrolental fibroplasia." This term is acceptable but we feel "persistence and hyperplasia of the primary vitreous" more accurately designates the lesion.

Terry employed the term "retrolental fibroplasia" to designate primarily a condition occurring bilaterally in premature babies after birth (not earlier than four months). He felt that this is a new, acquired condition different from the lesion which is unilateral at the time of birth in full-term infants. From the study of our cases and the literature we do not believe such a distinction is justified but that the same lesion may occur in both premature and full-term babies, that it may be unilateral or bilateral, and that all are congenital but may not manifest themselves until sometime after birth either because they are not looked for or because the lesion progresses.

AGE WHEN ABNORMALITY WAS OBSERVED

The age of the patient when the parents or physician first noted any ocular abnormality is stated in 15 of our records.

In nine patients the lesion was noted during the first week after birth:

<i>Number</i>	<i>Term</i>	<i>Noted</i>
<i>Cases</i>		
1	premature	at birth
3	full-term	at birth
1	full-term	on 2d day
1	full-term	on 3d day
1	full-term	on 4th day
1	full-term	within a week
1	premature	within a week

In six patients the lesion was noted at later dates:

<i>Number</i>	<i>Term</i>	<i>Noted</i>
<i>Cases</i>		
1	full-term	on 23d day
1	full-term	at 4 weeks
1	full-term	at 5 weeks
1	premature	at 10 weeks
1	full-term	at 4 months
1	premature	at 5 months

The records of the remaining 35 patients in some cases do not state specifically the time at which the parents observed something abnormal about the infant's eyes; in other cases the parents did not notice anything unusual until the baby was three months old or older, although they had suspected for a long time that the baby was not seeing things; however, they did not become seriously concerned until the baby was several months old.

On the basis of the embryology and pathology concerned, which will be discussed later, it is difficult to conceive of the tissue being absent at birth and forming subsequently. We know that remains of the hyaloid system and other congenital abnormalities in the structures of the eye are frequent accompaniments of the lesion. Our thesis is that in these cases the primary vitreous, which is a vascularized mesoderm, persists in some or all of its phases at birth and may show re-

gressive or progressive changes. Progressive changes, from the clinical aspect, may be due to actual hyperplasia of this mesoderm or to secondary factors such as hemorrhage, contracture, swelling of the lens, secondary glaucoma, and corneal opacity from contact of the lens and iris with the posterior surface of the cornea. The nature of these secondary changes will be pointed out when the pathology is discussed.

Prematurity. What constitutes a premature baby is not always clear. For our purposes we have chosen a birth weight of under five pounds or, in instances wherein the birth weight is lacking (15 of our cases), an infant born before a nine-months' period of gestation had been completed to designate prematurity. This criterion divided our 50 cases as follows:

30 (60 percent) were premature infants.

20 (40 percent) were full-term infants.

Laterality. Of 30 premature infants the involvement in 28 was bilateral; in 2 unilateral. In one of these there was a juxtapapillary area of chorioretinal atrophy in the fellow eye. Of 20 full-term infants the involvement in 7 was bilateral; in 13 unilateral. In one of these hydrophthalmos was present in the fellow eye.

Thus, of 50 cases, 35 were bilateral and 15 were unilateral.

Sex and color. Of 50 cases 31 were in males, 19 in females. All patients were white except in 1 case, a Negro.

Twins and Triplets. 3 cases were in twins, 2 cases were in 2 of triplets; the third sibling died at the age of three days and the ocular status was not known.

CLINICAL TYPES

The clinical appearance of this basic condition is varied and depends on several factors: (1) stage of cessation of the normal involution or disappearance of the

primary vitreous including the hyaloid system; (2) amount and character of the hyperplasia of the mesoderm of the primary vitreous; (3) extent and character of the secondary changes (hemorrhage, contracture, glaucoma, swelling of the lens, contact of iris-lens diaphragm with the cornea, and the like).

It is convenient to divide the clinical manifestations into four types as follows:

I. Saucer-shaped, whitish opaque tissue conforming to the posterior surface of the lens (figs. 1 to 5);

II. An opaque cornea, greatest in the central portion, usually associated with glaucoma, and maybe buphthalmos (figs. 6 to 9);

III. A localized area of opaque tissue on the posterior surface of the lens, or at the lens equator, or in the anterior vitreous, with or without retinal detachment (figs. 10 to 14);

IV. Remains of the hyaloid system (fig. 15).

These four clinical types are not necessarily sharply demarcated but may merge. Type I may change into type II, or there may be type I in one eye and type II in the fellow eye. Otherwise one type cannot go over into another type.

Type I. This appears as a concave, saucer-shaped whitish opaque tissue against the posterior surface of the lens (fig. 1). It is the typical and most frequent manifestation of the lesion. The globe is smaller than normal in size, the cornea is clear, and the anterior chamber shallow. The lens is clear, but against the convexity of its posterior surface is applied this whitish tissue whose surface is concave to fit the convexity of the lens. Blood vessels of varying size and number are usually visible in the opaque tissue. The tissue covers the greater part of the posterior surface of the lens, but the central portion is densest and there is a

Fig. 1 (Reese and Payne). Clinical type-I lesion. Above is shown the concave opaque tissue containing blood vessels which radiate from the center. The density of the lesion decreases from the center to the periphery, where it is more or less transparent. Below is shown the elongated ciliary processes inserted into the periphery of the retrolental opacity. This is the drawing of the left eye of the twin whose eye is shown in figure 14.

gradual thinning toward the periphery of the lens, where, frequently the fundus reflex, or even some details of the fundus, may be seen. Around the equator of the lens long narrow ciliary processes in one or more sectors can be seen either free or extending into the periphery of the membrane. These processes can usually be seen clinically (figs. 1 and 10) if looked for, and when present they are pathognomonic of this condition.

From this usual, clinical appearance, just described, there may be some variation, discussion of which follows.

The size of the globe was mentioned in the clinical description of 23 cases. Of these, the globes were larger than normal in both eyes in two bilateral cases; the globe was larger than normal in one eye

and smaller than normal in the fellow eye in one bilateral case. In all other cases, the eyes appeared to be smaller than normal. Microphthalmos was present in 7 unilateral cases and 12 bilateral cases. It was present in both premature and full-term infants.

It is felt that the enlargement of the globes was due to glaucoma. We found the intraocular pressure elevated in several cases of microphthalmos according to the tonometric readings. It is difficult to discuss glaucoma in these cases with confidence, owing to the fact that the tonometer discs and footplates are gauged for a normal adult cornea and not for the

Fig. 10 (Reese and Payne). Clinical type-III lesion without retinal detachment at two days of age (noted by father who is a doctor). At two months of age a hemorrhage was noted over the surface of the lesion and in the course of several weeks this hemorrhage became absorbed. After 1½ to 2 years the blood vessels disappeared, and now, at the age of 5 years, the lesion is the same size, somewhat less dense, avascular, and with a small localized almost chalky-white area interpreted as a focus of calcium deposit. This illustration was made when the patient was nine days old, and shows a vertically oval, whitish-opaque, vascularized lesion located on the posterior surface of the lens. Elongated ciliary processes are seen extending toward the lesion (case of Doctor M. U. Troncoso).

Fig. 2 (Reese and Payne).

A portion of a human eye showing persistence and hyperplasia of the primary vitreous corresponding to clinical type I. The retrolental fibrous mass is shown at A with the hyaloid artery at B. The lens is small. Ciliary processes, C and C', extend to the fibrous mass, and the retina is seen as far as D.

cornea of an infant or for a microcornea. In these cases the determination of the intraocular pressure by palpation is perhaps more accurate than by tonometer. Terry stated that "in spite of glaucoma the eyes have not become enlarged." This has been our experience provided we have been accurate in determining the presence of an increased intraocular pressure. We have the impression, however, that these eyes are not prone to develop buphthalmos in the presence of what seems to us to be a definitely increased pressure.

One of the most important factors in the production of glaucoma is the narrowing of the anterior chamber and blocking of the filtration angle due to advancement of the iris-lens diaphragm. This is produced by (1) swelling of the lens from an opening in its posterior capsule; (2) contracture of the fibrous membrane behind the lens, pushing the lens and iris forward (suggested by Terry in a personal communication); (3) massive hemorrhage in the vitreous. Another factor is the presence of an embryonic filtration angle in some of these cases.

The clinical appearance does not always remain the same but may present a changing picture. The later occurrence of glaucoma is particularly noted, and concurrent with this are usually a decrease or even a disappearance of the anterior

Fig. 3 (Reese and Payne). A section of a human eye showing persistence and hyperplasia of the primary vitreous corresponding to clinical type I. The large retrolental mass, A, extends for some distance forward into the lens, giving the lens a kidney shape. At B and B', rudimentary ciliary processes along with some of the retina extend to the periphery of the mass. An anterior pyramidal cataract is shown at C. A pupillary membrane is seen at D and D'. In the retrolental mass are large areas of cartilage, E, blood vessels, and the tissue at F is thought to be smooth muscle. Peripheral synechiae are present.

chamber, a stippling and opacity of the cornea of varying degree, and cataractous changes.

Hemorrhage may occur from the vessels in the opaque retrolental tissue. We have observed this clinically in three cases.

Typically, the retrolental tissue is concave (fig. 2), but this tissue may be sufficiently hyperplastic to extend into the lens substance and therefore present a

Fig. 7 (Reese and Payne). A section of a human eye showing persistence and hyperplasia of the primary vitreous corresponding to clinical type II. The retrolental fibrous mass is shown at A, and the posterior lens capsule is open from B to B₁. A higher magnification of this site is shown in figure 8. The ciliary processes, C, extend to the fibrous plaque. The lens is swollen and protrudes forward along with the iris to the cornea. *In vivo* the apex of the lens, along with the adjacent iris, rested against the cornea at D (see figure 9).

convex surface (fig. 3). Blood vessels may or may not be seen in the opaque tissue; if present they may disappear in time.

The lens may become cataractous preventing a view of the retrolental tissue. The cataract develops probably because the posterior lens capsule is opened (fig. 7).

Type II. This is characterized by an opacity of the cornea beginning in the central portion and spreading peripherally

Fig. 6 (Reese and Payne). Clinical type II. The opacity of the cornea is greatest in the central portion. There is diminished luster with stippling of the epithelium. The anterior chamber is absent where the lens and iris touch the cornea and extremely shallow elsewhere.

but always densest centrally (fig. 6). The anterior chamber is absent or shallow. The corneal epithelium shows stippling, more marked centrally and diminishing peripherally. Glaucoma is present and if of long standing there may be buphthalmos.

Fig. 9 (Reese and Payne). The gross appearance of the eye shown in figures 7 and 8. One side of the globe has been removed. The retrolental fibrous tissue is seen at A, with the hyaloid artery, B to B₁ coursing from the posterior surface to the disc. The zone of long ciliary processes extending into the retrolental mass is seen at C. The lens and iris extend forward to touch the cornea at D.

Fig. 15 (Reese and Payne). The clinical appearance of a case in which the features of clinical type IV dominate those of clinical type I. The patent hyaloid artery containing blood is seen extending from the disc to the posterior surface of the lens while along the posterior surface of the lens there is a fine lacelike pattern of fibrous tissue which might be interpreted as some persistence of the primary vitreous without hyperplasia. This is in contrast to clinical type I, in which the persistence

of the hyaloid system plays a secondary role. Clinical type IV in its most typical form is persistence of the hyaloid system without the retrolental lesion, just a clinical type I is the retrolental lesion without the hyaloid system (case of Dr. Charles A. Perera).

Type I may develop into type II. The corneal changes which dominate the clinical picture are due primarily to an advancement of the iris-lens diaphragm forward so that some of the iris and lens, and particularly the central portion, are in apposition to the posterior surface of the cornea (figs. 7 and 9). This interferes with the impermeability of the corneal endothelium, permits aqueous to enter the stroma, and produces changes leading to opacification, including pannus formation. The same advancement of the iris-lens diaphragm embarrasses the filtration angle and usually leads to glaucoma. The presence of increased intraocular pressure tends to increase the corneal edema. As previously mentioned in discussing glaucoma, the advancement of the iris-lens diaphragm is due to swelling of the lens, contracture of the fibrous sheath behind the lens, and perhaps intraocular hemorrhage. These factors will be considered further when the pathology is discussed.

The corneal opacity prevents an accurate view of the interior of the eye, and frequently the retrolental fibrous tissue is not visible, especially through the central portion of the cornea. The pres-

ence of a partially or totally cataractous lens adds to the difficulties. This type may occur in premature or full-term infants and may be unilateral or bilateral. When

Fig. 11 (Reese and Payne). Clinical type III lesion with retinal detachment. The fibrous plaque of tissue located at the posterior equatorial region of the lens is seen at A, and from it a fibrous extension, B, courses backward to the retina, which is detached. There was a partial coloboma of the optic disc. This patient, who has a similar lesion in the fellow eye, was one of triplets one of whom died and the other had persistence and hyperplasia of the primary vitreous clinical type I in one eye and clinical type II in the fellow eye.

Fig. 12 (Reese and Payne). A section of a human eye showing persistence and hyperplasia of the primary vitreous corresponding to clinical type III. From the retrolental fibrous plaque, A, a strand of tissue, B, crosses the vitreous to attach to the retina (see figure 13). Long ciliary processes, C, extend to the periphery of the retrolental tissue.

type I is present in the fellow eye the diagnosis is easier. This type is easily confused with congenital hydrophthalmos or buphthalmos.

Type III. This is seen as a localized mass of opaque tissue along the posterior surface (fig. 10), or the equator of the lens (fig. 11), or in the region around the base of the vitreous. This tissue may or may not have visible blood vessels, and if blood vessels are present they may in time disappear. Hemorrhage may occur in the tissue. If the lesion is located at the equator of the lens, or in the anterior vitreous around the base, it usually is accompanied by a detachment of the retina (fig. 11) which points toward the lesion; that is, the elevated retina extends toward or into the tissue, and the retina elsewhere may be in good position. A

hole in the retina or a disinsertion may be present. Long ciliary processes point toward the opaque tissue (fig. 10). Strands or fingerlike projections may extend from the mass posteriorly to the surface of the retina (figs. 12 and 13). In one case there was a coloboma of the optic disc.

Type IV. This comprises instances wherein the central portion of the hyaloid system, or the greater part of it, remains with little or no retrolental portion (fig. 15). This group is in contrast to type III, in which a part of the retrolental portion remains but no central hyaloid portion. The hyaloid system is a part of the primary vitreous so that anomalies of the two are associated with perhaps the one or the other dominant in an individual case. Just as there may be, on the one hand, an isolated rest of the primary vitreous on the posterior surface of the

Fig. 13 (Reese and Payne). The fibrous strand shown in figure 12 at B is seen here, B, attaching to the inner surface of the retina, which it is detaching by its pull at D.

lens, so there may be, on the other hand, an isolated remain of the hyaloid artery and all combinations in between the two extremes.

In our series, two particularly interesting cases belong to this fourth type. The one was of a 17-months-old infant who in the right eye had a massive vitreous hemorrhage preventing a view of the interior of the eye. The cause of the hemorrhage could not be determined until complete absorption occurred after several months, when a persistent hyaloid artery was found. The other was a similar case of a three-year-old boy who, on having the left eye bandaged after removal of a foreign body from the cornea, noticed that he could not see with the right eye. Under ether anesthesia, the eye was enucleated with the clinical diagnosis of retinoblastoma. Pathologic examination revealed a vitreous hemorrhage and remains of the hyaloid system; no tumor was present.

In these two cases vitreous hemorrhage occurred from a persistent hyaloid artery and no doubt spontaneously, as we know this does happen in other instances where elements of the primary vitreous persist.

The incidence of the four clinical types in our series of cases was as follows:

DIAGNOSIS

Clinical type I especially can be confused with retinoblastoma. X-ray studies on nine cases were negative for calcium. Transillumination of light is good except in those cases with hemorrhage. The most important diagnostic points are (1) an opaque tissue just behind the lens with a saucer-shaped or anterior concavity; (2) long ciliary processes extending into the retrolental tissue. Retinoblastoma seldom occurs in a microphthalmic eye. Clinical type II can be confused with other types of buphthalmos or with corneal changes secondary to intraocular inflammation. Clinical type III can be confused with massive retinal fibrosis of children secondary to intraocular hemorrhage at birth.²⁵

Type IV can be confused with an intraocular growth when vitreous hemorrhage occurs.

EMBRYOLOGY

The various phases of this basic lesion consist of arrested development, arrested regression, and hyperplasia of the developing vitreous. A review, therefore, of the development of the vitreous is in order.

FIRST PERIOD (up to the 13-mm. stage).
At the 4.5-mm. stage, mesoderm be-

Type I	Type II	Type III	Type IV
16 bilateral 8 unilateral	9 bilateral 1 unilateral	2 bilateral 1 unilateral	3 unilateral
2 bilaterallater progressed to type II			
4 with type I in 1 eye, and type II in the fellow eye			
2 with type I in 1 eye, andtype III in the fellow eye			
1 with type I in 1 eye, andtype IV in the fellow eye			

gins to appear in the space between the lens plate and optic vesicle. This mesoderm is part of the vasoformative cells which will grow in through the fetal fissure to form the hyaloid arterial system.

By the 10-mm. stage large quantities of vascular mesoderm have grown in between the lens vesicle and the inner layer (retina) of the invaginating optic vesicle, forming the hyaloid artery, which is entering the eye through the fetal fissure.

At the 12-mm. stage the vitreous is a mass of fibrils derived from the lens (ectodermal) and the retina (ectodermal) and joining up secondarily with fibrils (mesodermal) from the cells of the wall of the hyaloid artery.

At the 13-mm. stage the hyaline capsule surrounding the lens has completely formed. The lens no longer, therefore, contributes to the formation of vitreous. Vitreous fibrils, remaining adherent to the lens capsule, condense to form a thin fibrous envelope surrounding the lens and containing in its meshes the vessels of the vascular capsule. This fibrous capsule is the capsula perilenticularis fibrosa and originated from the lental part of the primary vitreous.

Development of vessels in the first period. At the 6 to 7-mm. stage the terminal part of the hyaloid artery ends near the posterior surface of the lens plate; it sends capillary branches into the meshes of the capsula perilenticularis fibrosa, forming a vascular net over the posterior surface of the lens. This is the beginning of the tunica vasculosa lentis, and is seen at the 8 to 9-mm. stage.

By the 10-mm. stage these vessels have extended anteriorly to form the lateral (equatorial), or capsulo-pupillary, portion of the tunica vasculosa lentis.

The vitreous as it now exists is known as the primary vitreous. It consists of ectoderm derived from the lens and retina, and of mesodermal vasoformative tissue

which has formed the hyaloid artery, the posterior and lateral portions of the tunica vasculosa lentis (enmeshed in the capsula perilenticularis fibrosa). The formation of the hyaloid capsule at the 13-mm. stage marks the end of the period of development of the primary vitreous.

SECOND PERIOD (12 to 65-mm. stage)

By the 16-mm. stage arterial branches arising from the hyaloid have begun to project into the freshly forming vitreous and are termed the vasa hyaloidea propria.

By the 25-mm. stage the anterior, or pupillary, portion of the tunica vasculosa lentis has formed.

Up to 40 mm. the vitreous (ectodermal and mesodermal) is still full of vessels as far as the periphery; that is, to the internal limiting membrane. The vasa hyaloidea propria have reached their maximum development.

After the 40-mm. stage the smaller vessels in the vitreous begin to atrophy, the portions nearest to the lens remaining visible the longest, with the result that the region nearest the retina becomes free of vessels. This avascular portion is known as the secondary vitreous. Its appearance is due to (1) atrophy of the proximal ends of the vasa hyaloidea propria and (2) further formation of additional vitreous from the retina as the eye enlarges.

There occurs a cessation of growth of the primary vitreous and a continued increase in the amount of secondary vitreous, filling the eye as it enlarges, thus giving a relative, but not an absolute, decrease in the size of the primary vitreous.

The condensation line between the primary vitreous and the secondary vitreous forms the "wall" of Cloquet's canal. In the canal passes the hyaloid artery from the optic disc to the posterior surface of the lens.

The primary vitreous is funnel-shaped,

narrow at the disc, and wide at the lens (fig. 16).

Fate of the posterior portion of the tunica vasculosa lentis and the vitreous vessels.

After the 20-mm. stage, the caliber of the vessels decreases.

At the 60-mm. stage, the vasa hyaloidea propria are the first to show signs of regression; they shrink in caliber first at their proximal ends (at their origin from the hyaloid artery), losing connection with the hyaloid artery. Their distal ends remain attached to the vessels on the posterior surface of the lens and tend to curl up.

By 8½ months, all vessels except the main trunk have atrophied completely.

During the eighth month the main trunk of the hyaloid artery becomes impervious in its central part; atrophy proceeds more rapidly in its proximal portion, so that it loses connection with the disc and floats freely in Cloquet's canal from the posterior surface of the lens; it also tends to curl up. This portion atrophies during the first few years of life.

PATHOLOGY

We have available 17 eyes which contribute to the study of the pathologic processes concerned in the condition under discussion.

I. THIRTEEN EYES FROM THIRTEEN DIFFERENT CASES OF PERSISTENT PRIMARY VITREOUS

A. The retrolental fibrous sheath. Each eye had a fibrous sheath of varied thickness and shape behind the lens (figs. 2, 3, 4, 5, 7, 9, 12). In most instances this sheath conformed to the contour of the posterior surface of the lens but occasionally the sheath was flat and rarely protruded inward, presenting an anterior convexity instead of an anterior concav-

Fig. 16 (Reese and Payne). The primary and secondary vitreous of a 130-mm. fetus as depicted on Tafel XXII in Bach and Seefelder's "Atlas zur Entwicklungsgeschichte des Menschlichen Auges," 1911. The hyaloid system, together with the primary vitreous, forms a vascularized, funnel-shaped zone of mesoderm extending from the retrolental region to the disc.

ity. The sheath was composed mostly of fibrous tissue rather rich in blood vessels. In seven of the eyes there was, along the posterior surface of the sheath, a definite layer which histologically resembled smooth muscle (fig. 8, D). This was thickest at the central area, where it merged with the remains of the hyaloid system when present (fig. 3, F). The staining reaction of this tissue with hematoxylin and eosin was consistent with that of smooth muscle, but with the trichrome stain it took more of a bluish color than adult smooth muscle but less than connective tissue. In three of the eyes, the sheath contained fat (fig. 8, C); in one, large areas of cartilage (fig. 3, E); and in one, an area of tissue interpreted as undifferentiated mesenchyme. Remains of the hyaloid system were noted in four eyes. This consisted of a patent vessel extending from the disc to the posterior central portion of the fibrous sheath. Very long slender ciliary processes extended to the periphery of the sheath in all eyes. These processes were enmeshed in the periphery

Fig. 8 (Reese and Payne). A higher magnification of the site from B to B₁ in figure 7. The opening in the capsule extends from B to B₁. The darker areas, A, represent calcium. The region designated C is fat, and the layer shown at D is smooth muscle. There are a considerable number of vascular channels.

of the retrolental fibrous tissue either on one or both sides of the sections, and in five eyes the retina also. In one eye (figs. 12 and 13) a fibrous strand coursed from the fibrous sheath across the vitreous cavity to the surface of the retina, where traction probably from contracture caused a detachment of the internal limiting layer of the retina (fig. 13, D). In two eyes there was evidence that the membrane had grown; in the one it had extended along the anterior hyaloid membrane for a short distance and in the other it had extended into the lens substance as papillary ingrowths.

B. The lens. The posterior lens capsule was open in seven eyes (figs. 7 and 8). In two eyes in which this was not seen, the capsule was thrown into wrinkles or folds, apparently from the contracture of the fibrous sheath along its posterior surface. This may explain the mechanism by which the capsule is broken. The subcapsular epithelium extended under the posterior capsule in multiple layers in five eyes and in one eye around the region of the broken capsule this epithelium had proliferated. Apparently from the opening in the posterior capsule the cortical area of the lens was cataractous in seven

eyes (fig. 7) and in one eye (fig. 3, C) there was an anterior polar cataract seen as a pyramidal-shaped extension due to proliferation of the subcapsular epithelium. In the cataractous cortical material large lens cells were present in two eyes. Other changes consequent to the opening in the posterior capsule were swelling of the lens and mild inflammatory reaction in the fibrous sheath adjacent to the opening, including some phagocytes containing soft lens matter. The lens in six of the eyes was definitely smaller than normal (fig. 2) and three of these were kidney-shaped, with the concavity directed posteriorly (fig. 3). In four eyes a portion of both the lens and iris were in contact with the posterior surface of the cornea (figs. 7 and 9), causing corneal changes consisting of edema, some infiltration by leucocytes, and early pannus formation. In one of these eyes the lens was dislocated into the anterior chamber and in another a swollen cataractous pyramidal-shaped lens protruded through the pupillary area to the cornea.

C. The retina. In eight of the eyes the retina was in place, appeared to have all of its elements, and no reason could be noted organically why it should not be

Fig. 4 (Reese and Payne). A section of a human eye showing persistence and hyperplasia of the primary vitreous corresponding to clinical type I. The retrolental fibrous tissue at A extends down into the funnel, B, of the detached retina, C. D represents subretinal hemorrhage, and E a retinal cyst. Elongated ciliary processes, F and F₁, extend into the retrolental tissue. The retina is composed of undeveloped embryonic tissue with true rosettes at G and elsewhere. This represents an instance wherein the secondary vitreous has failed to form.

capable of functioning. In one eye the retina although in place was definitely malformed, as evidenced by a deficiency in the nuclear elements, rods, and cones. In five of the aforementioned nine eyes the retina proper extended together with the ciliary processes into the periphery of the retrolental fibrous sheath (figs. 2 and 3). By contracture of the sheath the processes and retina seemed to have been drawn more and more toward the sheath. In only one eye had this process led to a slight detachment of the retina. This was only a small slit separation in the periphery on one side. In most instances the ciliary processes and retina were enmeshed in the sheath only on one side,

which was usually the nasal side. In three of the nine eyes the ora serrata of the retina extended to the base of the iris or to the ciliary processes on one side.

There were five eyes in which the retina was completely detached funnel-fashion, with the retrolental fibrous tissue occu-

Fig. 5 (Reese and Payne). A section of a human eye showing persistence of the primary vitreous corresponding to clinical type I. This is the left eye of a three-day-old premature girl obtained at autopsy. The persistent primary vitreous, A—A₁, extends down into the funnel of the detached embryonic retina, B—B₁, which contains true rosettes, C. The separation of the lens, D, from the retrolental fibrous tissue is an artefact.

This represents an instance wherein the secondary vitreous has failed to form. The right eye was of normal size and microscopically showed persistence of the primary vitreous, including the hyaloid artery.

pying the base and extending varying distances into the funnel (figs. 4 and 5). These five globes had identical pathologic changes and really constitute a distinct group. They are characterized by embryonic retina as a solid mass of tissue just behind the retrolental fibrous sheath. In this retinal tissue true rosettes were seen in four of the eyes and calcium deposit in three; four of the eyes showed subretinal hemorrhage which was of a massive nature in two; four of the eyes showed malformed and embryonic filtration angle, ciliary body, and iris. One of these cases (fig. 5) was of a 3-day-old premature girl, weighing 2,460 gm., whose eyes were obtained at autopsy. The right eye was of normal size and microscopically showed persistence of the tunica vasculosa lentis and some primary vitreous, persistence of the hyaloid artery, coloboma of the iris, pupillary membrane, retinal folds, and ciliary processes on the posterior surface of the iris. The left eye microscopically showed microphthalmos, persistence of the primary vitreous, embryonic detached retina with rosettes and calcium deposition, coloboma of the iris, pupillary membrane, and ciliary processes on the posterior surface of the iris. The autopsy findings were prematurity, congenital abnormalities of the heart (atrophy and stenosis of the pulmonary artery, hypertrophy of the ductus arteriosus, partial defect of the ventricular septum, right transposition of the aorta, and congenital dilatation and hypertrophy of the right side of the heart), congenital absence of the right hypogastric artery, congenital fracture of the right parietal bone, cranio tabes, congenital emphysema, congenital abnormality of the eyes, papilloma of the tongue, partial cleft palate, acute omphalitis, polydactylism of the right hand and both feet, physiologic jaundice, Meckel's diverticulum, accessory lobe of the spleen, accessory lobe of

the liver, uric-acid infarcts of the kidneys, bicornate uterus, and bilateral club feet.

These five eyes seem to represent instances in which the secondary vitreous failed to form. To summarize, therefore, this is a subgroup characterized by a persistence of the primary vitreous and failure of the secondary vitreous to form, detached embryonic retina, later perhaps subretinal hemorrhage, and frequently glaucoma. It may be that hemorrhage of the primary vitreous with organization and contracture also plays a part.

D. The iris and ciliary body. Some degree of pupillary membrane was noted in six of the eyes. (fig. 3). Both the iris and the ciliary body were rudimentary or underdeveloped in seven eyes and to a lesser degree in several others. As previously stated, the iris along with the lens was in apposition to the posterior surface of the cornea either in part or totally in four eyes. Peripheral synechiae were present in five eyes. The filtration angle was embryonic or underdeveloped in five eyes.

E. Glaucoma. There was histologic evidence of glaucoma in six eyes—peripheral synechiae in five, cupping of the disc in one, and hydrophthalmos in three.

II. TWO EYES FROM ONE CASE OF PERSISTENT PRIMARY VITREOUS INDICATING THE RELATIONSHIP TO HEMANGIOMA

Of twins born three months prematurely, one lived, and no abnormalities were noted except of the eyes. Clinically both eyes showed the following anomalies (fig. 1): the anterior chambers were almost absent and behind each lens there was a vascular, white, saucer-shaped sheath, and long ciliary processes were visible around the periphery. The diagnosis of persistent primary vitreous of each eye was made.

The other twin, who weighed 1 lb. 10 oz. at birth, showed, when several weeks old, an exophthalmos of the right eye. Examination of the interior of this eye showed a detachment of the retina above, with impaired transillumination over the detached area. Examination of the left eye was negative. After many attacks of cyanosis with cessation of respiration, the infant died, and an autopsy was performed.

The autopsy findings were as follows: prematurity; hemangiomas of the pharynx, carotid body on the right side, orbit on the right side, both retinas and adjacent vitreous, and choroidal plexus of the fourth ventricle; exophthalmos on the right side; extramedullary blood formation in the spleen, liver, adrenals, kidneys, and lymph nodes; splenomegaly; jaundice; lobular pneumonia of the right lower lobe; accidental involution of the thymus gland; accessory adrenal gland attached to the fallopian tube; and patent foramen ovale.

Microscopic examination of the eyes showed:

Right eye (fig. 14): The retina is detached over one half of the globe and there is a tear at the ora serrata which may be an artefact. Over the surface of the retina, and particularly of that portion detached, there are many blood vessels without much supporting tissue extending from the nerve head to a point just behind the ora serrata. These vessels and their supporting tissue are attached to the inner surface of the retina. There is some vitreous hemorrhage, which apparently came from the epiretinal vessels. The hemorrhage has become partially organized and the contracture of this, perhaps together with the supporting fibrous tissue of the vascular layer along the retinal surface, has led to detachment of the retina. At no point can excessive blood channels be seen in the fiber layer of the

retina. The filtration angle is embryonic in type.

Behind the globe there is a large non-encapsulated hemangioma (fig. 14, D containing large blood-filled sinuses sur-

Fig. 14 (Reese and Payne). The section of an eye of a three-month-old premature girl obtained at autopsy. The lesion corresponds to clinical type III. The twin of the patient lived and has typical clinical type-I lesions in each eye (see figure 1). Over the surface of the detached retina, A, is hemangiomatous tissue, B and B₁, in which is some hemorrhage. Contracture has detached the retina and thrown it into folds. A strand of fibrous tissue, C, extends from the hemangiomatous tissue to the posterior surface of the lens. D shows a portion of a typical hemangioma of the orbit which produced proptosis. The fellow eye showed a layer of flat, hemangiomatous tissue along the surface of the retina (see autopsy findings in text).

rounded by hyperplastic endothelial cells.

Left eye: The retina is in position, but along its entire surface there are small blood vessels either as a thin layer or as localized clumps, with relatively little sup-

porting tissue. These same vessels are also seen anterior to the nerve head. In places these vessels over the retina lie along the surface of the internal limiting membrane while elsewhere they appear in the nerve-fiber layer. Some vessels parallel the surface while others course obliquely or perpendicularly to the surface.

The angles are embryonic and the iris stroma appears more vascular than usual. The surface markings of the iris are obscured by a vascular tissue.

Pathologic diagnoses of eyes and adnexa were hemangioma of the right orbit; detachment of the retina of the right eye due to vitreous hemorrhage, organization and contracture from a hemangioma of the primary vitreous and vascular layer of the retina; and hemangioma of the primary vitreous and vascular layer of the retina of the left eye.

III. ONE EYE WITH A PERSISTENT HYALOID ARTERY FROM WHICH A SPONTANEOUS VITREOUS HEMORRHAGE OCCURRED

This is the globe removed from the three-year-old boy described under clinical type IV.

IV. ONE EYE OF A RED SETTER PUPPY SHOWING PERSISTENCE AND HYPERPLASIA OF THE PRIMARY VITREOUS

A white reflex was seen through the pupil and the eye was enucleated with the idea that the lesion might represent a retinoblastoma. Microscopic examination showed the typical lesion representing clinical type I.

ETIOLOGY

It is our belief that the lesion represents the congenital remains or persistence of embryonic tissue and, therefore, is not essentially an acquired one. Sixty percent of our cases occurred in premature in-

fants. We are inclined to believe that the same factor which precipitates early birth may also cause the eye lesions. Infection as the cause of congenital defects is receiving special attention now, due to the accepted connection between maternal rubella during pregnancy and congenital anomalies of the offspring; also toxoplasmosis may occur apparently in a subclinical form in the pregnant woman and produce congenital eye defects as well as choroiditis in the offspring, which may be born prematurely. One of our cases was of a premature boy whose right eye showed persistence and hyperplasia of the primary vitreous (clinical type I). The left eye, which was of normal size, showed an area of juxtapapillary choroiditis not unlike that caused by the toxoplasma.

We do not have convincing evidence indicating that the lesion occurs as the result of maternal infection. We obtained in 12 of the mothers a history of uterine bleeding ranging from the second to the eighth month. The duration varied from a day to several months. Three of the mothers with uterine bleeding also had upper-respiratory infections, with fever, and two mothers without uterine bleeding also had what was thought to be upper-respiratory infection.

TREATMENT

Surgery has been necessary for glaucoma 12 times. Iridencleisis, cyclodialysis, trephining, and iridectomy with sclerectomy have been tried; iridencleisis seems to be the most effective. The iris is usually friable, and a keratome section must be placed accurately because of the shallow anterior chamber. Because accurate examination, including tonometric readings, are not possible without general anesthesia valid results of the glaucoma surgery cannot be given.

On the premise that the retina seems

capable of functioning, judging by the microscopic examination of these eyes, an effort has been made to salvage vision in six eyes of six patients. The object has been to remove the lens substance by repeated discissions and finally to make a vertical cut in the retrolental fibrous tissue with de Wecker's scissors. When the discission is done the lens substance tends not to become opaque, swell, protrude into the anterior chamber, and be absorbed. Very little seems to happen when the lens capsule is opened. The capsule opening, therefore, can be made very extensive without fear of undue swelling. After it was thought that the lens substance had been dissipated for the most part, then a central vertical incision was made through the remaining tissue with de Wecker's scissors. This maneuver was followed by hemorrhage which filled the anterior chamber, but absorption took place in due time. In one instance three discissions and two incisions with de Wecker's scissors were necessary. In 2 of the 6 cases the mother states that the baby can pick up objects and believes this vision comes from the eye that was operated on. These procedures have never left the pupillary area completely clear, and leave much to be desired.

We intend to try irradiation on some of the selected cases as soon as the patients are older.

DISCUSSION

We have deduced from the clinical and pathologic findings that the basic lesion is a persistence in part or *in toto* of the primary vitreous (fig. 16) with or without hyperplasia and with or without secondary changes consequent to hemorrhage, opening of the lens capsule, and glaucoma. As the primary vitreous is mesenchyme it is not surprising that the various tissues into which the mesenchyme can develop are seen in the hyperplastic retrolental

tissue, to wit: fat, cartilage, smooth muscle, blood vessels, and connective tissue. Haden,²⁶ in his description of the embryology of the vitreous, states: "Toward the end of fetal life very little of the primary vitreous remains. Sometimes, however, this primary vitreous fails to absorb and the mesodermal part develops into fibrous connective tissue, and a firm, triangular, opaque mass is formed behind the lens. Ophthalmoscopically, this mass has been diagnosed as glioma of the retina."

There is a tendency for hemorrhage to occur in the persistent primary vitreous, and this may lead to organization, contracture, and their attendant sequelae. There is also frequently an opening in the posterior capsule of the lens, and this leads to cataract with lens swelling and perhaps some inflammatory changes. The corneal changes seen in clinical type II are due primarily to the entrance of aqueous into the stroma, caused by the contact of a portion of the lens and iris with the posterior surface of the cornea but augmented by the presence of glaucoma.

There seems to be evidence to indicate that the formation of the secondary vitreous plays a role in some of the pathologic findings. If fibrous strands of the primary vitreous remain adherent to the inner surface of the retina, then, when the secondary vitreous forms, the retina may be detached. All degrees of this process may be seen, even to the point where the primary vitreous is adherent to the entire inner surface of the retina and the secondary vitreous either fails to form or forms sparingly, with complete detachment of the retina.

There seems to be some relationship of the lesion under discussion to hemangioma. The primary vitreous is, for the most part, angioblastic mesoderm, and in some areas of microscopic sections

studied the retrolental tissue showed highly vascularized areas not unlike hemangiomatous tissue. Most hemangiomas encountered over the body are viewed as having their origin from congenital rests of angioblastic mesoderm. Basically, therefore, the relationship exists, and this is borne out by both our clinical and pathologic findings. We noted hemangiomatous lesions of the skin of the face, scalp, body, or extremities in seven of our cases. We also had a case with the clinical type I lesion associated with microphthalmos on one side and on the other side hydrophthalmos due, we thought, to hemangioma of the choroid together with a hemangioma of the skin of the upper lid. Furthermore, in describing our pathologic material we cited the autopsy findings in an infant with hemangioma of one orbit, both retinas and adjacent vitreous, and elsewhere over the body, whose pre-

mature twin had typical clinical type I lesions of both eyes. The fact that the basic lesion in both the persistence of the primary vitreous and in hemangioma consists of congenital remains of angioblastic mesoderm makes the two conditions fundamentally related.

We wish to express our thanks to Drs. R. Franklin, D. B. Kirby, J. H. Dunnington, C. A. Perera, R. G. Ingalls, R. C. Castroviejo, Olga Sitchevska, R. T. Paton, H. S. McKeown, E. L. Goar, T. H. Johnson, M. Uribe Troncoso, F. Barber, R. B. Thomas, and R. N. Berke for their kindness in allowing us to see their cases and to incorporate them in our work.

We are indebted to Miss Lily Kneiske for her assistance.

635 West One hundred sixty-fifth Street (32).

DISCUSSION

DR. IDA MANN (Oxford). I wish first to congratulate Drs. Reese and Payne on this interesting presentation of a very careful piece of work. These cases have been recognized since the middle of the 19th century and a great variety have been described, as it is doubtful whether any two cases are completely identical. The present collection and classification bring out very well the part played in their production by the primary vitreous and also their association with other developmental anomalies. These cases are all good examples of the general principle of the production of developmental anomalies through arrest at a definite stage of intra- or extrauterine life followed by aberrant growth. This aberrant growth may lead to excess normal tissue or, by atypical differentiation of pluripotential cells, to the appearance of tissue abnormal in that situation; for example, cartilage and unstriated muscle in the posterior vascular capsule. That prematurity is often a feature of these cases is not surprising since the interference with development seen in the eye may be part of a general aberration manifesting itself both as prematurity and in various associated malformations (for example, of heart, lungs, palate, and extremities as described by Dr. Reese). The primary cause of the whole clinical

picture is likely to be a maternal upset probably nonspecific in nature but specific in time. That this can happen has been shown by many experimental embryologists, and is now known to occur in man; for example, in rubella cataract and in the maldeveloped retinae of fetuses x-rayed *in utero*. I would therefore like to suggest to Dr. Reese that it would be more helpful if he would consider classifying his cases not on clinical findings alone but into groups based on the probable stage in development at which the initial arrest occurred. Judging the cases from a purely embryologic standpoint I should say his subgroup of type I begins earliest, probably at about the 15-mm. stage and certainly before the end of the organogenetic period. May I also urge in the description of this group the use of the term "failure of coaptation of the retina" in place of "detachment"?

His type III is also early, beginning certainly before the third month and is allied to congenital retinal septum, which can also be explained as a localized linear failure of secondary vitreous.

Type II probably begins between the fifth and sixth months, as there seems to be an accompanying arrest of formation of the angle of the anterior chamber, while those cases of type I which subsequently develop glaucoma arise pos-

sibly only a little later. Type IV is obviously related to an arrest at the very end of fetal life only (during the eighth month).

This classification could be checked and amplified if very accurate data could be obtained of the time of the maternal upset as evidenced by the occurrence of bleeding and of respiratory infections noted in 14 of the mothers. The cases would then probably be seen as a continuous series rather than as sharply differentiated types.

DR. HENRY HADEN (Houston, Texas). Dr. Reese and Dr. Payne are to be congratulated upon this comprehensive study.

I agree with them that the term persistence and hyperplasia of the primary vitreous is appropriate for the congenital abnormalities under discussion. The primary vitreous is composed of mesoderm which flows in between the rim of the optic cup and the lens, the mesoderm that accompanies the hyaloid artery as it passes through the fetal fissure into the optic cup and ectodermal fibers derived from the lens and inner wall of the optic cup.

Toward the end of fetal life the mesodermal part of the vitreous disappears, and the permanent vitreous is exclusively ectodermal in origin. Under certain circumstances a portion of the mesodermal tissue is not absorbed, and a variety of lesions such as Dr. Reese and Dr. Payne have described are the result. The size, position, and style of the lesion are influenced by the fetal age at which the normal recession of the primary vitreous ceased.

I do not see why one should look farther for the nature of these congenital anomalies. A glance at a few sections of the developing vitreous should make this clear.

DR. F. H. VERHOEFF (Boston, Mass.).

I think this is a very interesting and instructive demonstration. In specimens sent me for examination by the Army Medical Museum I have seen all of the conditions described by Dr. Reese. I was particularly interested in his finding of cartilage in the tissue. In the Army Medical Museum a recent specimen, which I had believed to be unique, showed this even better than the one he demonstrated on the screen.

Dr. Reese spoke of hemorrhages occurring in some of these eyes. I should like to ask him if he has ever seen hemorrhage extending from the retrolental tissue into the lens. I have seen this in at least one case.

I think his classification is a most useful one, and in the future will prove of great assistance in the description of such cases. To follow Dr. Mann's suggestion, all he will need to do is to assign certain embryonic periods to the stages he has mentioned.

T. L. TERRY (Boston, Mass.). That Drs. Reese and Payne hold certain views in disagreement with mine is encouraging. What stimulates search for an unknown truth more than theories that are at variance! I am sure that we shall find mutual pleasure and satisfaction in working out an agreement as full understanding of the process is attained.

Their belief that the abnormal development occurs before birth is the most outstanding difference. The evidence is based on one instance in which the infant weighing 3 lbs. 5 oz. was observed on the day of birth to have the disease process well developed. Warkany has proved that the young born of rats in an extreme stage of vitamin-A deficiency develop abnormal eyes early in gestation. We have confirmed his findings. Chief among these abnormalities is the growth of mesodermal tissue in the meshwork of the tunica vasculosa lentis behind the

lens. Although such extreme depletion of vitamin A is not likely in the human, it could cause such a sequence of events. It may account for the lesion on which Reese and Payne base their conclusion of intrauterine development of the process in their most dramatic case.

The process can and does develop during intrauterine life. It has been observed in full-term infants at time of birth. I agree with Reese and Payne that this is probably a process identical with that seen in the premature infants, but I do not believe we have proof yet that they are identical. The frequency of the disease is greater the more premature the infant. The lantern slide shows graphically the increase of frequency of the process the more prematurely the infants are born. The causes of prematurity in infants with and without the ocular malady are not greatly dissimilar, and in many instances the cause is unknown. In some of the instances of spontaneous prematurity the mother had no illness and no known disability before the premature birth. I would expect the ocular defect to manifest itself at birth or very soon thereafter in premature infants nearing term, whereas in the infants weighing three pounds or less, it would not appear for weeks or even months. It is to be regretted that Reese and Payne did not indicate the stage of prematurity of each of their cases.

A routine study of the eyes of premature infants, followed from day of birth to a time when all danger of retrolental-fibroplasia development has passed, has shown me that this disease process can and does become manifest in some premature infants after birth. Dr. Stewart Clifford, who follows closely the premature infants after their incubation, has referred a case to me in which the retrolental tissue was a small opaque spot in the back of the lens resembling a giant

Mittendorf's dot. In one week this opaque area had increased so that it covered perhaps half of the back of the lens, and the anterior chamber was becoming shallow. At the end of the second week the chamber was becoming more shallow. The opaque tissue covered the entire posterior lens surface. I have seen two other such cases. Clifford and I have seen other cases jointly in which the eyes looked normal at birth, but after the patients' discharge from the hospital the opaque retrolental tissue developed and the anterior chamber became obliterated, although we did not see these patients while the fibroplasia was developing. Clifford and I have not been able to determine during their incubation which premature infants will develop retrolental fibroplasia, but Clifford has shown that some 12 percent, or one out of eight, will develop it some weeks or months after birth.

When the true nature of this condition is fully understood, there will be a satisfactory explanation for isolated observations which now seem in conflict. As has been said often, full-term birth is, indeed, only an incident in life, but in extremely premature birth there is a tremendous revolution of physiologic processes. The organs of digestion, respiration, temperature regulation, internal secretion, and even the eyes are called upon to function. An abnormal process can be instituted by this precocious function sufficient to cause such an aberration of ocular development. Why both eyes or the eyes of both twins are not uniformly involved is another puzzling finding in the present state of our ignorance. The view that there is an external exciting cause for this abnormal development and that the most common single factor in many of the individuals who develop it is extremely premature birth produced by a variety of causes, leads to a definite ex-

perimental and investigative approach.

According to Clifford, the only associated defect is the lack of mental development present in some of these infants. The occurrence of angioma I first noted in a patient from Havana, one whom Reese may also have seen. Since then I have found angioma in 16 additional cases. I have not found any statistics showing the frequency of angiomata in infants as a whole, although I am told it is high.

A less important difference in our views is that of terminology. The disease, I believe, represents a growth of embryonic connective tissue in the mesh of the closed tunica vasculosa lentis, which, in part, concurrently or later, reopens before its lumen has become impervious. I say "reopens" because the vessels of the tunica-vasculosa-lentis system had previously been observed when the eyes of extremely premature infants were first examined and had become invisible when they stopped carrying blood. It is not a persistence of the vascular tunic in its embryonic and early fetal state in a region where no such solid tissue is ever encountered during normal development. Thus, I object to the "persistence" used in the title, which the essayists suggest. I consider primary vitreous to be the total mass of mesodermal and ectodermal syncytium between the lens and the retina up to the 40-mm. stage. That blood vessels are a part of it I do not agree, although blood vessels for a time pass through it and perhaps contribute to its early growth. When the blood vessels disappear, I do not visualize the primary vitreous changing over to secondary vitreous, but it persists throughout life as the less viscous material filling the so-called retrolental space and Cloquet's canal. In this view, Prof. Ida Mann told me she was in agreement. If it is correct to consider the hyaloid artery and

tunica vasculosa lentis to be an integral part of primary vitreous, then the name "Hyperplasia of the primary vitreous" loses much of its objection to me. Primary vitreous reaches its full growth at the 40-mm. stage. Were the vitreous a perfect sphere, instead of part of a sphere, its total volume would be less than .420 c.mm. The volume of the adult vitreous approximates 4,300.00 c.mm. If the retrolental fibrous proliferation represents a hyperplasia of the primary vitreous, even though it does not permeate the entire vitreous of these small eyes, it would represent a very great hyperplasia indeed. Exception might be taken to the length of the name suggested by Reese and Payne. Of all the terms formerly used, "fibrovascular sheath" is perhaps the least objectionable, but it does not locate the disease process in any one organ of the body nor in any position in the eye, as does "retrolental fibroplasia."

That a name like "retrolental fibroplasia" is needed is shown by the frequent repetition of some such terms as "retrolental fibrous mass . . . fibrous membrane back of the lens . . . retrolental tissue . . ." occurring sometimes more than once to a page in the essay of Reese and Payne.

Because of the slow manner in which the lens material is absorbed following discussions, probably the result of reduced production and accumulation of aqueous humor in the eye, I have been eradicating the lens by a linear extraction associated with an iridectomy above and an iridectomy below in an attempt to prevent blocking of the pupil. I have used this operation only when the anterior chamber is absent, lenticular-corneal synechiae are present, and central corneal opacities are developing. An injection of normal saline solution into the anterior chamber demonstrated the presence of

these conditions. Careful suturing of the wound permits the retention of injected air in an attempt to prevent recurrence of the anterior synechiae. Following the operation an adequate anterior chamber is usually present.

The suggestion of irradiation to close the blood vessels in the fibroplastic tissue is a sound one which I shall try.

The essay of Reese and Payne indeed contains a great deal with which I fully concur. The quality of their illustrations deserves the highest praise.

DR. REESE (closing). We stated that our classification was purely a clinical one and adopted for convenience sake. I think Dr. Mann's idea to make the classification include the stage at which the maldevelopment in the embryo occurs is well worth while. I agree with her that the term "detachment of the retina" employed with respect to our subgroup of type I might more accurately be replaced by the term "failure of primary coaptation of the retina."

We appreciate very much Dr. Haden's beautiful sections showing the embryology of the primary vitreous and the manner in which it undergoes involution.

Dr. Verhoeff mentioned the relationship to hemangioma. I stated that our conception of a hemangioma is that it represents a congenital rest of angioblastic mesoderm which later begins to grow into a neoplasm. It does not behave like a true neoplasm clinically because angiomas do not have as a rule the capacity for unlimited growth. I tried to point out the fundamental relation of hemangiomas and this lesion and to give what evidence we have that the two may be associated.

We tried to point out what evidence we had of the relationship of the lesion under discussion and infection. We do not believe that this evidence is convincing.

We have never noted hemorrhage extending from the retrolental tissue into the lens as Dr. Verhoeff has.

We believe this lesion is congenital irrespective of whether it occurs in premature or in full-term infants. The matrix of the lesion is present at birth with varying degrees of hyperplasia subsequently. This interpretation is not based solely upon one case as stated by Dr. Terry but upon several factors. First, in premature infants the lesion was observed at birth in one case and at less than one week of age in one case; in full-term infants the lesion was noted at birth in three cases and at less than one week of age in four cases. The clinical and pathologic features appear identical in both groups. Second, the hyaloid artery, if absent at birth, never develops later; rather, if it is observed later it was necessarily present at birth. In other words, the hyaloid artery is always a congenital manifestation. The hyaloid artery is frequently associated with the condition under discussion. Third, the various tissues (connective tissue, blood vessels, fat, cartilage, and smooth muscle) seen in these lesions take origin from mesoderm. Mesoderm does not form after birth.

Dr. Terry disagrees somewhat with our conception of the primary vitreous. It seems to me our views in this regard are the ones generally advanced by the embryologists. Irrespective of names there certainly occurs in embryonic life an angioblastic mesoderm inside the eye and normally this disappears. When it persists and becomes hyperplastic we believe it gives rise to the various lesions described in this general group.

Dr. Terry refers to a case in which he observed an increase in an island of retrolental tissue resembling a giant Mittendorf dot. One of our cases (fig. 10) was perhaps similar when first observed a few days after birth. After four

years our case showed no increase in size, and the blood vessels disappeared.

Dr. Terry's case in which he observed the development of this lesion from birth is difficult to explain on the basis of our conception of the lesion. I imagine it can be explained on the ground that there was a small area of that retrolental tissue present and this showed an unusual degree of rapid hyperplasia.

If anyone plans to study this basic lesion experimentally we think the dog might be a good medium. We base this on the fact that we have seen a typical type-I lesion in a red-setter puppy. This puppy had a white reflex in the pupil, and because of the possibility of retinoblastoma an enucleation was done. Sections showed typical retrolental fibrous tissue with a hyaloid artery.

GRADUATE TRAINING IN OPHTHALMOLOGY*

SECOND JACKSON MEMORIAL LECTURE

HARRY S. GRADLE, M.D.

Chicago

It would seem most fitting and proper that the subject of a Jackson Memorial Lecture should pertain to the question of ophthalmic education, a topic most dear to the heart of Dr. Edward Jackson. He himself lived through the era of the development of modern training, for in his early days organized teaching was non-existent in the United States. He saw the vicissitudes and struggles of the early aspirant for ophthalmic training, and he saw the gradual emergence of ordered American ophthalmology from the chaos of the last century.

Before the turn of the century there was no formalized training in ophthalmology in the United States. True it is that many a good ophthalmologist was developed during those days, but it was by preceptorship, in the more or less haphazard clinics of that day, or in private offices, supplemented by personal non-supervised reading. The amount of training that a man could obtain depended upon his personal energy and ambition.

The more fortunate journeyed to Europe, to the clinics of Vienna, Berlin, Paris, and London. In many instances they were lucky enough to obtain volunteer assistantships for one or more years, but in the majority of cases they merely observed the work as it was performed by the regular personnel of the clinic. These clinics were fairly well organized, and the native men obtained their training in ophthalmology by serving as assistants for 5 to 10 years. But still there was no formalized course of training in ophthalmology, here or elsewhere.

The foreign study and the influence of the foreign clinics became manifest here about 1900. In many of the large cities ophthalmic clinics had been in operation for 30 or even 40 years, but they were not well organized, and the majority required assistantships or internships in both eye and ear, nose and throat. In fact, in practically all of the universities those chairs were combined, as they were in the clinics. But the spirit of ophthalmology was becoming apparent in the rank and file, and that spirit demanded adequate didactic and clinical facilities for its expression. Nor could that spirit be denied, and during the next 15 years the develop-

* This lecture was to have been read before the 1945 meeting of the American Academy of Ophthalmology and Otolaryngology, which was cancelled on account of the National Emergency.

ment of ophthalmic clinics and ophthalmic residencies progressed with startling rapidity. Ophthalmology became divorced from otolaryngology and succeeded in freeing itself from the dominating influence of its big brother, general surgery, so that the chair of ophthalmology in the medical schools became a separate entity. But still there was no formalized training in ophthalmology.

Then came the advent of the American Board of Ophthalmology, formed jointly by the three national societies, for the purpose of introducing standards into the training and practice of the specialty. Some years elapsed before the Board realized its importance, and formulated its aims, but almost overnight its educational influence became manifest. The requirements set up tentatively by the Board gave the ophthalmologic candidates a definite idea as to the course of study it was necessary to pursue; an idea that in the past had been a mere will-o-the-wisp. They perceived the goal of a completely rounded ophthalmologic education, and although formalized and supervised training was still lacking, they were able by industrious reading to form a fairly solid foundation upon which to build clinical training.

Gradually, formalized training began to make its appearance here and there. In one clinic, a course of lectures would be given upon basic subjects, while in another the clinical aspects were treated didactically as well as practically. A postgraduate school developed a course of training in ophthalmology in which didactic and laboratory work was given simultaneously with some clinical training. And so under the influence of the Board the progress has been continuous, and throughout the country more and more opportunities are being developed for serious training in ophthalmology—training that will fit a man to become a safe and sound special-

ist, upon whom his people and his colleagues can rely.

Still the opportunities for formalized training in ophthalmology are below the nation's requirements. It has been estimated that a minimum of 200 ophthalmologists a year are required to maintain the present quota; but it is also agreed that the current number of qualified ophthalmologists, certificated or otherwise, is far below the number required by the population of the United States. At present the opportunities for thorough training in ophthalmology, basic, didactic, and clinical, number about one quarter of the requirements. Another half obtain training through clinical residencies, but without basic or didactic instruction. The remainder pick up what they can.

To the American Board of Ophthalmology is due unstinted praise for its efforts and accomplishments. But the Board is ever-changing, and although universally recognized, it has no authoritative standing or academic backing. So it would seem that the time has come to incorporate the achievements and work of the Board into such form as to insure perpetuity for the ideals and accomplishments that have done so much to advance ophthalmology in this country. Such solidarity can be attained only through academic connections, and to that end it would seem fitting and proper that the gap that exists between requirements for graduation from the medical school and the certification by the American Board of Ophthalmology be filled by the university. Upon the university should fall the responsibility for formalized training in ophthalmology for a sufficient number to fill the needs of the country.

In general, formalized education in the universities is held at two main levels, the undergraduate school culminating in a Bachelor's degree and the graduate school culminating in a Doctor's degree. Above

that level the universities offer training only on a research or a personalized basis.

During the past 25 years the need has arisen for a third level of university training, particularly as it pertains to medicine and the medical specialties. This level should cover the period between completion of the general internship and the completion of training required by the specialty boards. That period of training, which, in the majority of cases, is now more or less haphazard, is definitely a function of the universities, and when assumed by them will take on a systematized character more or less standardized, as is the present work in the undergraduate medical schools.

The gap that exists between the completion of the year of internship and the attainment of the certificate of the Board is at present the major deficit in ophthalmic education, and there is no uniformity in the endeavors of the various institutions to fill that gap. One offers a one-year clinical residency without didactic training in any of the basic sciences; another considers a two-year clinical residency with a minimum of basic-science training sufficient; while at the other end, is the five-year residency with complete and adequate basic training. Because of the chaos that exists under the present system, or lack of system, it is very evident that the gap should be filled under university jurisdiction and that a certain degree of uniformity in ophthalmic training on a nationwide basis should be introduced. Regimentation should, of course, be avoided, but a formalized curriculum could serve as a basis for training which would be varied in the universities and their associated institutions according to existent facilities.

Let us see how such a plan might function in our own specialty of ophthalmology, a specialty which is probably best prepared to institute a regular uni-

versity program of graduate teaching.

It must not be forgotten that there are two classes of men who demand training in ophthalmology: those who intend to pursue an academic career of investigation or teaching, and those who intend to devote themselves to the clinical practice of ophthalmology. The first group is small in number and can be handled adequately by each institution as the case arises, and consequently requires but scant attention here. The second group outnumbers the former by a hundred to one, and hence requires more intensive study and more extensive facilities. To that group are dedicated the following pages.

Before acceptance of a student into the training realms of ophthalmology, rather extensive psychologic and psychometric tests are in order, to prove the fitness of the candidate for the specialty. Included should be tests for manual dexterity, the *sine qua non* of an ophthalmic surgeon. Good vision, normal color perception, and perfect stereopsis are even more essential to the art of eye surgery than they are to the piloting of an airplane.

Upon completion of the general interne year, a period of instruction in the basic sciences so requisite to a well-grounded ophthalmologist, should follow. It should be given within the university walls and be operated as a regular class of the medical school. The length of time would, of course, vary with different institutions, but in no case should it be less than three months nor more than six. The course should be an elaboration into detail of the basic sciences of ophthalmology as taught to the undergraduate medical student, and to that end would require a mixed faculty. The general aspects of anatomy, physiology, optics, chemistry, and bacteriology should be presented by the undergraduate teachers of those subjects in the undergraduate laboratories, whereas the application of those subjects

in the realm of ophthalmology should be presented by clinical ophthalmologists who have devoted special attention to those sciences. Lectures should play but a small role in such instruction, and the major pedagogic methods should be those of laboratory demonstrations and directed conferences and quizzes. The study of pathologic anatomy should be instituted toward the end of such a basic course, for there should be no contemplation of clinical ophthalmology until after conclusion of the basic course.

The candidates are then ready to enter the period of clinical training, which should be not less than two years. Obviously, the university hospitals cannot accommodate the total number, and extramural expansion is necessary. That can be accomplished by bringing into the fold such nearby general hospitals as offer an adequate residency in clinical ophthalmology, and supplementing that clinical work with university instruction. For example, there are in Chicago six large general hospitals that have clinical residencies in ophthalmology of one year each, one man at a time. These should take two residents for two years each, staggered so as to provide a senior and a junior, who have gone through the basic course at the university. The university hospitals in Chicago can take eight residents per year, with the result that each basic course would have 20 candidates.

Whether the resident were serving in the university or in an affiliated hospital, the instruction should be the same, and should be given in the early evening after the clinical work for the day is finished. At least once, and preferably twice, a week the group should assemble at the university for clinical or pathologic conferences or seminars. For such conferences, held under the direction of experienced clinical teachers, a two-year program should be prepared in advance, and

the junior group and the senior group should be kept separate; otherwise one year would be merely a repetition of the preceding. At each conference the prescribed reading for the next conference should be given, and thus each resident could prepare himself in advance. The conferences and seminars should embrace the clinical aspects of ophthalmology from beginning to end, borderline topics, the relationship of ophthalmology to other medical specialties, and social and preventive ophthalmology. Pathologic conferences should be held at least once a week under the ophthalmic pathologist, and each resident should be given prepared sections and clinical histories of cases, upon which he should present a prepared report at later conferences. Those studies should continue uninterruptedly throughout the entire two years of clinical residency.

Upon conclusion of the two years' clinical residency with its associated factors, a comprehensive oral and clinical examination should be given the residents by the combined staffs of the university and affiliated hospitals; including demonstrations of surgical ability upon animals and patients. Successful completion of such examination should entitle the resident to a higher degree, possibly Doctor of Science in Ophthalmology, and the automatic award of the certificate of the American Board of Ophthalmology, whose examinations would then be confined to men whose training had been other than the prescribed university course.

Now let us see what this would do for the training program on a nationwide basis. As of December, 1941, there were opportunities for approximately 180 men to be trained each year in ophthalmology, of whom about one third received adequate basic and didactic instruction, the remainder receiving clinical training only.

Under the proposed plan, at least 35 of the Class A medical schools could and probably would participate, taking in a class of 10 to 20 men each year. That would mean 400 to 700 men adequately trained in ophthalmology each year, as contrasted with the figure just quoted. Of the 3,500 or more approved hospitals in the United States, sufficient clinical residencies in ophthalmology can be developed to take care of the extramural aspects of the program.

Approval of this plan by the American Board of Ophthalmology and by the various teaching institutions could lead to an early establishment of this or some simi-

lar system. The University of Illinois has authorized the Department of Ophthalmology to set this plan into operation as soon as the teaching members of the ophthalmic staff are released from military service and full ophthalmic residencies are again functioning. Thus it becomes very possible that within the course of a few years, there may be attained the adequate formalized training in ophthalmology of numbers sufficient to supply the needs of the country, fulfilling the hopes of our great teacher, the late Edward Jackson.

58 East Washington Street (2).

REPORT FROM THE WILMER INSTITUTE ON THE RESULTS OBTAINED IN THE TREATMENT OF MYOPIA BY VISUAL TRAINING*

ALAN C. WOODS, M.D.

Baltimore, Maryland

The purpose of this paper is to report the results of an investigation on the effect of visual training in uncomplicated myopia. The participation of the Wilmer Institute in this investigation was limited solely to examination of the patients before the beginning of the training, and again after the training had been completed. The pre- and posttraining examinations were made in the Wilmer Institute by staff members under the direction of Dr. Frank B. Walsh. The training program itself was conducted in another part of Baltimore, remote from the Johns Hopkins Hospital, under the direction of Dr. A. M. Skeffington, Director of the Graduate Clinic Foundation of Saint Louis, Missouri, and his associates. The Wilmer Institute therefore acted solely as a judge of the effect obtained, and so

acted without either endorsement or condemnation of the visual training conducted by Dr. Skeffington and his associates. The background leading up to this investigation was as follows:

In the spring of 1944, the Curtis Publishing Company, through the agency of Mr. Bruce Gould, offered to finance an investigation on the merits of widely publicized methods of visual training in the treatment of myopia. The fundamental idea of this investigation was to collect a suitable group of patients with uncomplicated myopia, have their visual acuity and refraction errors determined prior to the course of visual training, and at the conclusion of such training have the patients examined to determine if any demonstrable improvement in the vision or underlying myopia had occurred. To this end Mr. Gould proposed to bring to Baltimore several leading advocates and exponents of the training therapy, which

* From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University.

gentlemen would establish a clinic in Baltimore where such treatment could be properly pursued. The Wilmer Institute was requested to act as judge of the results obtained. After preliminary discussion, the Wilmer Institute accepted this proposition under the following specific conditions:

The candidates for training would be recruited by Dr. Skeffington and his associates, and sent to the Wilmer Institute for a preliminary examination. After this examination candidates showing any ocular pathologic change or who did not appear suitable for such treatment would be rejected by the examining physician in the Wilmer Institute. The nature of the eye examination to determine the visual acuity, refractive error, and the like, was entirely at the discretion of the staff of the Wilmer Institute, with the agreed stipulation that recognized standard tests and standard illumination would be employed. The results of the preliminary examinations were not to be transmitted to Dr. Skeffington or his associates, but were to be filed with the Curtis Publishing Company. The selected patients would then be given such visual training as Dr. Skeffington and his group believed proper, the staff of the Wilmer Institute having no knowledge of the type or extent of such training. On the completion of the course of visual training, the patients would be returned to the Wilmer Institute for a second examination. In certain cases, notably when some improvement was noted, the patients might again be returned to the Wilmer Institute for a third examination to determine whether the observed improvement was maintained. It was agreed that the results of these examinations should be tabulated and reported by the Director of the Wilmer Institute in a recognized medical periodical before they were reported or referred to either by the Curtis Publishing Com-

pany or Dr. Skeffington's group. The Wilmer Institute received no financial support of any kind from the Curtis Publishing Company or any other agency. These conditions were agreed to by the Curtis Publishing Company, by Dr. Skeffington's group, were approved by several leading ophthalmologists who were consulted, and the investigation was undertaken.

Accordingly, in September of 1944, Dr. Skeffington and his associates moved to Baltimore and established a clinic in the downtown section of the city. The patients for examination were recruited chiefly from the public schools of Baltimore, with the inclusion of a few private patients and nine candidates who were midshipmen from the United States Naval Academy in Annapolis. These patients were then sent to the Wilmer Institute for examination, and 103 were selected as having uncomplicated myopia and being proper candidates for training. The patients were then returned to Dr. Skeffington for training. On the completion of the training they were then returned to the Wilmer Institute for the posttraining examination. The training clinic continued in operation until December of 1944. The final, third examinations on the patients showing improvement were completed in May of 1945.

TECHNIQUE OF EYE EXAMINATION

First examination. Each patient referred to the Wilmer Institute as a candidate for training under this program was subjected to the following examinations.

1. Determination of the visual acuity without correction of each eye at 20 feet or a shorter distance when necessary. Four charts were used for this purpose: (a) Snellen chart with letters, (b) Snellen chart with numbers, (c) Landolt broken-ring chart, and (d) Snellen letter-E chart. In this examination, as in all tests of

visual acuity, the individual was required to declare that smaller objects could not be seen, or must consistently make comparable errors in stating what was seen. The amount of illumination was between 24 and 26 foot candles, and this was constantly checked.

2. A cycloplegic was then instilled in the eyes. Two instillations of 5-percent homatropine were used in individuals nine years or over. Atropine sulfate, 1 percent solution three times a day for two days, was used in younger individuals. The eyes were then retinoscoped and the static refraction was determined.

3. A general external and ophthalmoscopic examination was made to rule out any ocular pathologic process.

Second examination. The visual acuity without correction was again made on the four separate charts as in the first examination. In 67 instances further retinoscopic determination was made.

Third examination. The visual acuity without correction was determined as in the first two examinations.

TECHNIQUE OF VISUAL-TRAINING PROGRAM

The visual-training program which these patients received is summarized by Dr. Skeffington as follows:

"The visual training rests on the postulate that seeing is a learned act and is therefore susceptible to training. A system of differential analysis was employed to discover the type of distorted pattern resulting from undesirable visual practices. Spheres, cylinders, prisms, and targets were employed in this training program with the idea of reorganizing the visual behavior patterns that the visual skills, including acuity, can be improved significantly. This method of visual training has neither in theory nor practice any relation to the so-called Bates theory, and in theory and practice it involves no deviation from the known and accepted theories

and facts of physiology and neurology of the eye or the experimental psychology of vision. It has its inception in the work of optometrists, stemming from the standard literature on learning. The records of this development from its start exist in the optometric literature, and are covered in the papers of Drs. George Crow and Harry Fuog, S. K. Lesser, Leslie B. Burdette, Marguerita Thoma Eberl and others, in the Optometric Extension Program, articles on training in the files of the Optometric Weekly, the American Journal of Optometry, and other publications."

TABULATION OF RESULTS

The full information on every patient is contained in the final table IX. It will be noted that there were marked fluctuations in the visual acuity of the majority of the patients on different charts. It was impossible to average these different visual acuities on the Snellen scale. Therefore, each observation on the Snellen scale was reduced to percentage visual acuity, using the tables computed in Dr. A. C. Snell's book on "Medico-legal ophthalmology." The pre- and posttraining visual acuity was arrived at by taking an average of the percentage visual acuity as determined on the four charts. The results reported, whether they be improvement or diminution of vision after training, are therefore an increase or decrease in the percentage visual acuity, and not the percentage of gain or loss of vision.

From the statistical viewpoint, this method of reporting results leaves much to be desired. Primarily, as will be hereafter pointed out, it weights the scales in favor of improvement according to the degree of myopia. Secondly, grouping the patients according to the results involves the fallacy that each group contains individuals with all degrees of myopia. However, attempts to group the patients according to the degree of myopia

Average.....	29.76	22.97	54.5	52.3	24.7	29.3

resulted in a multiplicity of small tables which were meaningless. Further, since some patients had high degrees of anisometropia, the patient as an entity could not be grouped under one heading. The attempt to group the material under "eyes" rather than patients, completely ignored the individual subjective element. Although the patients in each of the four

groups varied somewhat in the degree of their myopia, nevertheless, as will later be pointed out, the average percentage visual acuity of groups I and II was low, of group III was in the mid-zone, and of group IV was high. Therefore, despite the fact that grouping the patients on the basis of results rather than degree of myopia involves a statistical fallacy,

* The tables for this article were set up and provided for our use by the Transactions of the American Academy of Ophthalmology and Otolaryngology.

nevertheless the different groups roughly reflect different average levels of myopia, and this method appears to be the fairest and best calculated to give an accurate over-all picture.

RESULTS

On the basis of the average pre- and posttraining percentage visual acuity, the

acuity, or patients who showed an improvement in one eye and a loss of visual acuity in the second eye, irrespective of the degree.

IV. Patients who showed a loss of 10 points or more in the percentage visual acuity of one eye, while the second eye was either stationary or likewise showed some loss in percentage visual acuity.

TABLE II.
Results of Third Test Three Months After Completion of Exercises.
Patients Showing Improvement In All 4 Charts.

Cases	Improvement of Percentage Visual Acuity on 2nd Test		Final Improvement of Percentage Visual Acuity on Third Test

107	27	26	31	35
Average.....	29.4	34.5	19.8	17.4

patients fall into four definite groups. These are:

I. Patients who showed a consistent improvement in each eye on all four charts.

II. Patients who did not show a consistent improvement on all four charts, yet in whom the over-all average in the percentage visual acuity after training was at least 10 points better in one eye than the pretraining figure, and in whom the second eye was at least no worse, irrespective of the fact that on one or more charts the posttraining vision was not improved, or might even be below the pretraining level.

III. Patients who showed no practical change in the eyes after training. This includes patients in whom the observed increase or decrease in vision was less than 10 points in the percentage visual

GROUP I

There were 30 of the 103 patients who showed a consistent improvement in each eye, on all four charts, of over 10 points in percentage visual acuity. The average results of these 30 patients are shown in table I.

Thus, the average improvement in percentage visual acuity in the right and left eyes was, respectively, about 24.7 and 29.3 points. This corresponds to an average improvement of reading about one to three additional lines on the Snellen charts, depending on the degree of myopia, a patient with high myopia, having a pre-exercise acuity of 20/200 and a post-exercise acuity of 20/100, showing 28 points of improvement, whereas one with low myopia, having 20/50 pre-exercise acuity and 20/20 posttraining acuity, showed only 22 points of improvement,

despite the more spectacular improvement on the Snellen scale.

A consistent effort was made to have each of these 30 patients return for a third examination to determine to what extent the improvement observed on the second examination had been maintained. These efforts were successful in only nine instances. The remaining 21 patients

had either disappeared or had lost interest and did not respond to the request to return. A comparison of the gain over the pretraining level showed by these nine patients is set forth in table II.

In these nine patients the average gain in percentage visual acuity disclosed on the second examination in the right and left eyes was, respectively 29.4 and 34.5

points. On the third examination, performed from three to five months after the second examination, this had dropped to 19.8 points in the right eye and 17.4 points in the left eye. In two patients (1 and 107) the improvement noted on the second examination had, on the average, been maintained. In the remaining seven, the observed improvement had declined.

GROUP II

There were 31 patients who, while they showed no consistent improvement on all

patient (60) had lost two thirds of the observed improvement. One patient (127) had lost two thirds of the improvement noted in the right eye, and all the improvement in the left eye. The remaining three patients (41, 79, and 110) had lost all of the improvement observed in both eyes, the final figures being actually below the pretraining level although the diminution was in no case significant. The final average gain of these eight patients was six points in the right eye and 1.9 points in the left eye. In short, the average percentage visual acuity was essentially unchanged.

TABLE IV.
Results of Third Test Three Months After Completion of Exercises In Patients Showing Inconsistent Improvement On Four Charts.

Cases	Improvement of Percentage Visual Acuity In 2nd Test		Final Improvement of Percentage Visual Acuity On Third Test

four charts, nevertheless showed an overall average improvement of at least 10 points in one eye, and no loss in the second eye. The average records of these patients are set forth in table III.

The average improvement of percentage visual acuity of these 31 patients was 13.0 points in the right eye and 16.4 points in the left eye. Eight of these patients returned for a third examination, three to five months after the completion of the training. A comparison of the gain disclosed in the second examination against the final change shown in the third examination is shown in table IV.

Three patients (9, 20, and 70) had roughly maintained the improvement observed on the second examination. One

GROUP III

There were 32 patients in this group who showed only minor change in the visual acuity after visual training. The changes noted were: (a) either less than 10 points in the percentage visual acuity either on the plus or minus side in each eye, or (b) a variation of greater than 10 points plus in one eye while the second eye showed a loss in percentage visual acuity. The average swing in these 32 patients was +4.1 points in the right eye and +2.4 points in the left eye. No attempt was made to bring these patients back for a third examination. The average figures for these 32 patients are shown in table V.

GROUP IV

There were 10 patients who showed a diminution in the percentage visual acuity in both eyes after visual training. As already stated, these changes on the minus side were insignificant, and well within the subjective margin of error. The changes averaged -12.7 points in per-

centage visual acuity in the right eye, and -8.9 points in the left eye. The average figures for these 10 patients are given in table VI.

A summary of these four groups is shown in table VII.

A number of these 103 patients, 67 in all, were again retinoscoped under a

cycloplegic on the second examination after completion of the eye exercises. A comparison of the pre- and postexercise retinoscopies is shown in table VIII. It is immediately apparent that the visual training had produced no change in the basic myopic error. The occasional minor changes noted are those which would result in variations of the action of the cycloplegic.

COMMENT

It is not within the scope of this report to discuss any theoretical merits or demerits in the visual-training program detailed in the optometric literature and used on these patients, or to comment upon other popular theories which have at one time or another been advanced in support of the treatment of myopia by eye exercises or visual training. While

we did determine the retinoscopic error in a number of the patients before and after the visual training to ascertain if any change had occurred in the basic refraction, and we likewise followed with interest changes in the psychologic reaction of the trainees toward their visual handicap, nevertheless our chief objective in this experiment was to determine if the visual training produced any significant alteration in the visual acuity of the trainees. The complete data from which conclusions on the latter point are drawn are given in table IX. Comment here is limited to statistical criticism of these data, and to observations on the reaction of the patients to the visual training.

Primarily, this study is *per se* uncontrolled. A proper control would be a

group of myopic individuals of similar age and degree of myopia whose visual acuity without correction was determined at the times of the first and second examination and who were not subjected to visual training and did not wear glasses. However, the absence of a control group is unimportant. Every ophthalmologist will concede that within a three-months' period without any treatment, a group of 103 myopic individuals would show no significant improvement in their uncorrected vision. The one pertinent question is, therefore: Are the changes in the percentage visual acuity noted in these patients of any significance? These figures disclose several points pertinent to this question.

First. The uncorrected visual acuity varied within wide limits in individuals with approximately the same degree of myopia. For example, patients 1 and 14 with approximately the same degree of myopia (—1.75D. sph. and —1.75D. sph. = —.25D. cyl. ax. 80°) had 16/200 and 20/200 vision, whereas 63 and 79, with myopic errors of —1.75D. sph. = —.25D. cyl. ax. 180°, showed visual acuity of 20/100 + 1 and 20/100. The average percentage visual acuity of these four

patients with practically identical refractive errors was, respectively, 13, 24, 42, and 42, a swing of 29 points. Similar variations (table IX) occurred in all grades of myopia. The visual acuity of any myopic person is obviously influenced by a large subjective element—the individual interpretation of a blurred retinal image.

Second. There was often an amazing swing in the percentage visual acuity of the same individual on the same day when vision was tested on different charts. This, for example, was exhibited in case 5, wherein percentage visual acuity, varied from 20 to 41; case 8, from 20 to 58; case 17, from 1 to 49; and case 57, from 8 to 73! Swings of from 20 to 30 points in the different charts were the rule rather than the exception in patients with an average percentage visual acuity in the mid-range. This swing was irregular, some patients doing better on one chart than on another.

Third. The method of computing the results on the basis of a change in the percentage visual acuity weights the scales in favor of an improvement according to the severity of the myopia. Thus an individual with high myopia who has an initial 10/200 vision has a percentage

visual acuity of 3, and is theoretically capable of a 97-point increase in the percentage visual acuity, whereas one with a low-grade myopia whose uncorrected vision is 20/30 has a percentage visual acuity of 92 and is susceptible of an improvement of only 8 points in the percentage visual acuity. This statistical fallacy appears to be clearly reflected in the results. Thus, in groups I and II, where the greatest improvement in the percentage visual acuity was noted, the myopia was most severe, the initial average visual acuity of both eyes being 27.3 and 23.2, respectively, in the two groups. In group III, where there was no essential change, the myopia was less severe, the average percentage visual acuity being 40. In group IV, where there was an actual, although not significant, loss in the percentage visual acuity, the average myopia was of low degree and the average percentage visual acuity before exercises was 75.1. In short, the lower the initial percentage visual acuity, the more room there was for improvement, and the more likely improvement would result from any educational process. The higher initial percentage visual acuity, the less room there was for improvement and the less chance there would be for an educational procedure to produce improvement.

The first two points, the variation in visual acuity of myopic individuals with the same refractive error, and the swing in the same individual on different charts, in themselves disclose a margin of error in subjective testing sufficient to account for the average improvement observed in groups I and II. The third point, the weighting of the scales in favor of an improvement in those with high myopia, may also be a factor in the improvements shown by the patients in these two groups.

However, the fact remains that approximately 60 percent of the patients did show moderate to slight improvement

in the percentage visual acuity after the visual training. The essential question is whether this low-grade improvement (groups I and II) and the occasional more spectacular individual improvement (cases 3 and 4) are to be explained entirely on the basis of individual fluctuations and a statistical presentation or is any credit to be given to the visual training to which the patients were subjected?

I have already pointed out that the average degree of improvement noted in groups I and II was within the limit of error of subjective testing and the individual interpretation of a blurred myopic visual image. However, it was the general impression of the examining physicians that after the eye exercises a great number of the patients were more careful in the interpretation of their visual impressions. Just how far careful study of a blurred visual image will result in an improvement in the subjective visual acuity can readily be demonstrated on any aphakic individual of ordinary intelligence. In an aphakic individual with 20/15 corrected vision in each eye, the introduction of +1.00 spheres before his correction will immediately reduce the visual acuity to about 20/40. However, with a few minutes' careful study of an unknown letter chart or a broken-circle chart, such an individual will be able to decipher the 20/20 line accurately. Similarly, the introduction of +2.00 spheres, giving a false myopia of -2.00 diopters, reduces vision to 20/100, but after a few minutes' study the patient can identify symbols on the 20/50 line. In short, the subjective determination of the vision of a myopic person on the Snellen chart is, within certain limits, a test of the individual's ability to interpret correctly the blurred visual impression received on the retina. In so far as any form of visual education aids an individual to the maximum utilization and correct interpretation

of a blurred retinal image, such procedures are of value. There are obviously definite limits within which such education is possible. For example, this visual-training program appears to be of little value to individuals unable to pass the visual requirements of the United States Naval Academy. There were nine such individuals in this group of trainees and only in one instance (4) was the improvement sufficient to allow the candidate to pass the Naval Academy examinations, although in one other case (3) the candidate came close to the passing level. However, the more the initial interpretation of a visual sensation is faulty, the more unstable or careless the individual is in his visual habits, the more room and hope there is for an improvement as a result of education.

The different examining physicians were impressed by a psychologic improvement in a number of patients. Some patients while exhibiting no material change in their visual acuity, were nevertheless convinced they saw better and that they used their eyes with greater satisfaction to themselves. There were no psychiatric examinations on these patients, but the examining physicians all agreed that this psychologic improvement was more noticeable in those individuals who appeared somewhat emotionally unstable. It should therefore be conceded that the visual training, in so far as it produced a psychologic change in the patients toward their visual handicap, was of benefit to the patients.

Therefore, while it is admitted that within narrow limits there may be some educational merit to this visual training, and that in impressionable individuals there may be some beneficial psychologic change, the results of this study give little comfort to the advocates of this method of treating myopia. The visual gains resulting from this training were small and not

constantly maintained. The visual training had no effect on the basic myopia as determined by retinoscopy. The results of this experiment indicate that the visual training is of no value in curing myopia.

SUMMARY AND CONCLUSIONS

A series of 103 myopic individuals were selected from a total of 130 applicants. The uncorrected visual acuity of these patients was recorded, a cycloplegic instilled, and the retinoscopic and static refractions determined. These 103 myopic persons were then returned to a group of optometrists and psychologists for a course of visual training designed to improve their uncorrected vision. At the end of this visual training the patients were again examined to determine what change had occurred in their uncorrected vision. It was found that 30 of these patients, or 29 percent, showed a low-grade improvement on all charts. This improvement averaged an increase of 27 points in the percentage visual acuity. A second group of 31 patients, or 30 percent, did not show a consistent improvement on all four charts but did show an overall improvement in both eyes which averaged 14.7 points increase in the percentage visual acuity. As far as could be determined the improvement in these two groups was not consistently maintained. A third group of 32 patients, or 31 percent, showed practically no change in the percentage visual acuity. A fourth group of 10 patients, or 9 percent, showed a decrease in the percentage visual acuity of 10.8 points.

The changes in the percentage visual acuity noted was found to lie within the limits of error of subjective testing of the visual acuity. Also the estimating of change on the basis of percentage visual acuity weights the scales in favor of improvement in those who have high myopia.

The maximum average increase noted in group I was between one and three lines improvement in the Snellen scale. It was believed by the examiners that education in the correct interpretation of a blurred visual image was the chief factor in the improvement noted in this group. It was further believed that the exercises produced a beneficial psychologic reaction in certain patients toward their visual handicap, regardless of

whether an actual improvement in visual acuity had occurred.

With the possible exceptions of educating some patients to interpret blurred retinal images more carefully and of convincing some others that they could see better even though there was no actual improvement, this study indicates that the visual training used on these patients was of no value for the treatment of myopia.

EYE CONDITIONS AMONG CHILDREN OF PREMATURE, FULL-TERM, AND HYPERMATURE BIRTH*

THOMAS H. EAMES, M.D.

Boston

The frequent appearance of amblyopic school children whose history records premature birth suggested the possibility that such children's vision might mature more slowly than that of others. A preliminary study¹ of 100 poor readers revealed a markedly higher incidence of premature births than is usually encountered in the general population. Furthermore, 31 percent of the children born prematurely were found to have defective vision.

Since then 619 children have been studied, of whom 155 were born before the completion of the normal term of pregnancy or weighed $5\frac{1}{2}$ pounds or less at birth.[†] They were compared with 439 children who were born at full term or whose birth weight was more than $5\frac{1}{2}$ pounds. Both of these groups were compared with another composed of 25 children born during or after the tenth calendar month of pregnancy. The age range in all groups was from 5 through 17 years. The writer's primary interest in

the subject centered on the educational implications for children from first through twelfth grade and only those whose ages corresponded to this range were admitted to the study.

All of the children were given complete eye examination, and measurements of visual acuity, refraction, and muscular imbalance were taken. The visual-acuity and muscular-imbalance measurements were made with the refractive correction in use. In addition other physical defects and diseases observed during eye examination were recorded.

Comparison of the groups without reference to age revealed 28 percent *more* children with vision of 20/30 or less among those born prematurely. The frequency difference was the same for each eye but for both eyes together the difference was 24 percent. The same group presented 4 percent *less* hypermetropia in the right eye and 12 percent *less* in the left eye, but displayed 9 percent *more* myopia in the right eye and 8 percent *more* in the left eye. The groups showed little or no difference in the incidence of either hypermetropic or myopic astigmatism. They also displayed no difference in the

* From the School of Education, Boston University.

† The children considered premature in time were 8.0 months of term or less.

incidence of either esophoria or exophoria of five prism diopters or more in distance vision but exhibited 4 percent *less* esophoria and 1 percent *less* exophoria in near vision.[†]

The central tendency of the examination results were studied in terms of median.[§] The premature group exhibited a median visual acuity (with correction) of one Snellen line *poorer* vision in the left eye only. No other important differences in the medians were noted in any of the fields of investigation.

All of the cases of both premature and full-term birth were next distributed according to age. This necessarily provided smaller numbers of cases at each age level and limited the study to that extent. However, age comparisons have shown interesting trends which are worth considering.

The frequency of vision of 20/30 or less was found to be higher in the premature group at *all* ages, for each and for both eyes together. There was a *higher* incidence of low vision in the left eye among the premature cases at the 6-, 7-, and 12-year levels, and at the 6-, 7-, 9-, 10-, 11-, 14-, and 16-year levels among the full term cases. The premature group exhibited a *higher* frequency of low vision in the right eye at 17 years. It appears that there is a general tendency toward more frequent low vision in the left eye in both groups, but this tendency was greater among those who were not premature. With age, both groups dis-

played some tendency toward a decrease in the frequency of hypermetropia and an increase in that of myopia in both spherical and astigmatic refraction. The premature group presented a general tendency toward a *lower* frequency of hypermetropic astigmatism in each eye at the ages from five through eight years. The frequency of exophoria in distance vision, among the premature cases, was *lower* until the age of nine years. From 10 to 13 it showed less difference from that of the full-term group, but at the age of 14 it rose sharply above their level and tended to remain elevated through age 17. The frequency of exophoria in near vision tended to increase with age in both groups after the eighth year. The premature children exhibited a tendency toward a greater incidence than did the others. No marked difference between the frequencies of esophoria in distance vision was noted, but the premature group showed a consistently *lower* frequency of esophoria in near vision.

The study of central tendency by age levels revealed a consistently *lower* median visual acuity through the ninth year in the premature group and a median visual acuity of one Snellen line *poorer* vision in the left eye in each group at the sixth year. The median myopia tended slightly to show an *increase* from the fifteenth through the seventeenth year among those prematurely born. Measurements of muscular imbalances were distributed on either side of the zero or orthophoric point, with exophoria on one side and esophoria on the other. This was done so as to take into account all the cases instead of studying exophoric and esophoric cases separately without regard to the cases of orthophoria. This seemed wise since measurements of muscular imbalances are commonly taken in degrees or prism diopters of deviation from the orthophoric or mid point on the whole

[†] Muscular-imbalance measurements for distance vision were taken at 20 feet. For near vision the test distance was determined by the body build of the child, the reading or near distance being such that the arm formed a right angle with the forearm while the book was being held.

[§] The median is the position in a distribution where the middle case falls. It is superior to the arithmetic mean (average) because one or two abnormally high or low scores do not distort the expression of central tendency. For this reason a truer indication is provided.

scale from exophoria through orthophoria to esophoria or vice versa.

The medians in the two groups differed little in tests at 20 feet, both falling either in the orthophoric range or in one of the low exophoric intervals. No esophoric medians appeared in either group in distance or in near vision. The medians for near vision were in the orthophoric range

difference being in feeble-mindedness, which occurred 3 percent *more* frequently among the children born prematurely. They also exhibited a little less than 2 percent *more* nerve diseases and dysfunctions as a group and speech defects than did those born at full term. No instance of vertical muscular imbalance occurred in either group, a finding which tends

in both groups from five through seven years. Exophoria in near vision appeared first among the premature individuals at eight years and one year later among those born at full term. Although the premature group exhibited some tendency to manifest a *larger* median exophoria as age advanced, the full-term group showed little or no tendency to do so.

Other conditions noted during eye examination are presented in table 3. The frequency differences between the two groups were not marked, the greatest

to confirm the very low incidence of this type of defect among the school children whose eye defects have been studied previously by the author.

The tendency toward more frequent and sometimes greater degrees of defectiveness among those prematurely born raised the question as to whether children born after an abnormally long pregnancy might show defects and deficiencies. Accordingly the full-term and premature groups were compared with another composed of children born during or after

the tenth calendar month. The small number of cases permitted only a consideration of the total group. These children, termed the Hypermature Group, presented consistently higher frequencies of low vision, hypermetropia, and exophoria, and *lower* frequencies of myopia and esophoria than did the full-term group. They also exhibited consistently

higher incidences of hypermetropia and exophoria, and *lower* frequencies of low vision, myopia, and esophoria than did the premature group.

It was noted that the frequency of low vision in the left eye was *higher* than that of the right eye in this group as well as in the others. Whether this general tendency results from the predominance of

right eyedness or from some other cause or causes is a matter for later investigation.

There was no difference in any of the visual-acuity medians in any of the three total groups, but the hypermature group presented a *greater* median spherical hypermetropia than did either of the other groups and the same median muscular

imbalance as the premature group. It appears, then, that the hypermature cases tend to present a frequency of low vision midway between the full-term and premature groups; a higher incidence of hypermetropia and exophoria than either of the others, and muscular imbalance at near which is about as great as that in the premature cases but more frequent

TABLE 3
COMPARISON OF THE EYE CONDITIONS OF CHILDREN OF PREMATURE AND FULL-TERM BIRTH

than in either the full-term or premature groups. The complete data are presented in table 4.

The outstanding facts disclosed by the present study are the *higher* frequency of poor vision among children of premature birth at all of the ages from 5 through 17 years, and the *poorer* median visual acuity of the same group through the ninth year. While this is true of the cases involved in this particular investigation it suggests the probability that many prematurely born children enter school before being ready visually to compete with normally seeing children and go through at least four or five school years before attaining 20/20 vision. Other conditions tending to occur more frequently or to a greater degree among those born prematurely emphasize the less rapid development of this group. These findings do not support the gener-

ally held belief that the ill effects of prematurity are overcome quite early in life and are of no particular importance thereafter. Apparently, there is a tendency for visual handicaps to persist into the middle grades. It is also notable that a small group of children of hypermature or late birth presented defects and deficiencies which led one to think that hypermaturity may prove to be somewhat similar to prematurity as an initial handicap.

SUMMARY

One hundred fifty-five children who were born before completion of the normal term of pregnancy or who weighed $5\frac{1}{2}$ pounds or less at birth are compared

with 439 children born at full term or with a birth weight of more than $5\frac{1}{2}$ pounds. These two groups are compared with a smaller group of children born during or later than the tenth calendar month. The outstanding tendencies noted are the higher frequency of low vision at all of the ages studied among those born prematurely and the poorer median visual acuity through the ninth year in the same group. The presence of somewhat comparable defects and deficiencies in both the premature and hypermature groups provides a suggestion that hypermaturity may prove to be of similar but probably less importance than is prematurity as an initial handicap.

VISION IN INDUSTRY*

IRVING B. LUECK, B.S.
Rochester, New York

In a report of the Committee on Industrial Ophthalmology of the Section on Ophthalmology of the American Medical Association, read before the fourth annual Congress on Industrial Health in Chicago, January 13, 1942, the scope of industrial ophthalmology was divided into five interrelated parts, as follows:

1. The efficient use of vision in industry.
2. Eye accidents—their prevention and the treatment of injuries.
3. Conservation of visual health.

4. Visual economics—the effect of vision on earning ability and on production.
5. Medicolegal ophthalmology.

The report goes on to state that the most neglected field of industrial ophthalmology relates to efficient visual performance (items one and four, above), and that the study of visual effectiveness includes the following topics:

1. Basic elements of visual performance—the need of standards for essential functions of vision for specific jobs.
2. Methods and techniques of testing.
3. Ways and means of correcting visual defects.

*From the Bausch and Lomb Optical Company. Read before the fourteenth annual Mid-Winter Post-Graduate Clinical Convention in Ophthalmology and Otolaryngology, Los Angeles, California, January 22, 1945.

4. Placement of employees according to visual qualifications.
5. Health factors that influence vision.
6. Programs of coöperation between management, employees, industrial medical departments, and ophthalmologists in establishing practical methods of visual testing, correction, and placement.

In studies of the first four of these topics, the chief interest has lain in the individual visual differences of people; for people differ—by nature, training, education, and inclination.

The economic significance of these individual differences is appreciated by management, because a misplaced employee brings about many complications. Management knows that the outputs of identical machines, manned by different operators, are seldom the same. Some operators may be trying to work beyond their capacity. Some are poor producers, some good, some superior. Some have many accidents, some few, some none. Too, recent legislation has made difficult the promiscuous hiring and firing that was easily possible a dozen years ago, and employers today have a higher sense of social obligation. Hence, the consideration of individual differences in the selection of applicants for placement on any job is becoming more and more important.

There have been numerous excellent studies in this field both in this country and in England.^{1,2,3} The work of the past five years has been largely in the realm of testing methods and in the actuarial approach to the factual interpretation of visual problems in industry. In applying the facts disclosed by such study, industry is uncovering many employees who must be referred for professional attention. It is, therefore, imperative that ophthalmologists know about this fact-finding pro-

gram and the varied visual needs of industry.

The mention of visual needs of industry probably immediately conjures up in the reader's mind a picture of the norms with which he deals daily, in terms of 20/20 Snellen acuity at distance, orthophoria at far, six prism diopters exophoria at near, and so forth. No such inflexible standard of perfection applies in industry any more than does a standard of physical fitness which would require each person to have a head size of exactly 67%. Whether in industry, or elsewhere, according to Snell,⁴ "Good vision is that degree of visual functional ability which is adequate to perform the visual task presented." This definition should be kept in the forefront, for it removes the rigid standards of previous thinking and substitutes the standard that fits each case. It eliminates the idea of one standard of perfection—good distance acuity on the Snellen chart—which has led personnel placement astray in its attempt to allocate employees properly to jobs.

Almost every job requires some visual skill. Some jobs require very highly developed visual skills. Certain skills must be more highly developed than others for some jobs. For example, such a skill as good distance acuity, which is necessary for the crane operator, is contraindicated for the hosiery looper or radio-tube assembler who requires good near acuity. A negative correlation has been found between distance acuity and production in looping hosiery.⁵ There are, then, jobs that require certain skills and for which other skills are not required.

Researches conducted (and continuing) in various industries on thousands of employees by Professors Tiffin, Wirt, and co-workers of Purdue University, and Dr. Hedwig S. Kuhn, have shown that of all the tests that have been tried there

are 12 measures of individual differences that are most useful in correlating visual skills with performance on the job. Seven of these are distance tests and five are near tests.⁶

1. Vertical heterophoria—far
2. Lateral heterophoria—far
3. Binocular acuity—far
4. Right-eye acuity—far
5. Left-eye acuity—far
6. Color discrimination
7. Vertical heterophoria—near
8. Lateral heterophoria—near
9. Binocular acuity—near
10. Right-eye acuity—near
11. Left-eye acuity—near
12. Stereopsis

The individual differences disclosed by these tests are certainly revealing of some facts which have not been fully appreciated in the past. As an example, suppose that several milling-machine operators

Fig. 1 (Lueck). Relation between near vertical phoria and rated success for milling-machine operators. From Tiffin and Wirt, in *Jour. Consult. Psych.*, 1944, v. 8, pp. 80-89.

from a nearby plant present themselves for visual rehabilitation, and in the course of the examination disclose a hyperphoria of the right eye. The refractionist's tendency would be to correct it in the spectacle lenses by prescribing the necessary amount of prism, base down,

in the right lens. Yet such action might seriously disturb those men on the job, cause lower production, and increase spoilage. Facts gathered seem to indicate that a hyperphoria of the right eye can be tolerated on the job, whereas a hyperphoria of the left eye cannot be tolerated (fig. 1).

This should have been anticipated, now that we know the facts, from a close

Fig. 2 (Lueck). Relation between age and visual discrimination at near. The two peaks occur at the age at which the average man obtains his first bifocals and at the age at which he obtains his second and last pair. From Tiffin,¹⁰ "Industrial psychology," p. 150.

study of how a milling-machine operator holds his head in watching and setting the machine. Over a period of years he develops this hyperphoria as an occupational characteristic peculiar to this job, and until milling machines are redesigned to eliminate this phenomenon of "right eye up," milling-machine operators will continue to develop this tendency.

Another interesting comparison, of the many that might be drawn, is one which relates the number of persons, passing a simple near-acuity test, with age. This comparison shows graphically a fact long known to manufacturers of bifocal lenses, and one affecting the relative numbers of different segmental additions made and

stocked. People put off getting bifocals. Kuhn⁷ states that patients are too often aided and encouraged in this practice by the prescribing of the "compromise" lens.

Fig. 3 (Lueck). Relation between age and distance visual acuity. From Tiffin, "Industrial psychology," p. 149.

Further, people in general make an average of two trips for professional attention after presbyopia becomes noticeable. One trip is made between the ages of 45 and 55 years, and a final trip between the ages of 60 and 65. The curve in figure 2 discloses that presbyopia is already affecting some individuals at the age of 35 years. The trend of diminishing near acuity is not arrested by increasing use of spectacles until about age 50; and even with whatever reading glasses and

Fig. 4 (Lueck). Relation between age and use of spectacles for general wear by high-rated and low-rated employee groups. From Tiffin, "Industrial psychology," p. 145.

bifocals are procured, this loss in near acuity is never fully compensated in any typical industrial group. Obviously, there is need for more attention to patients requiring bifocals, and need for better publicization of the potentialities of multifocals. There is a need for the greater use of trifocals to raise the acuity-performance level. Trifocals are often indicated at about age 50 when the nearest point of clear vision through the distance lens is beyond the farthest point of clear vision through the near portion. The shift from bifocal to trifocal should be seriously

Fig. 5 (Lueck). Relation between age and use of spectacles for near vision by high-rated and low-rated employee groups. From Tiffin, "Industrial psychology," p. 146.

considered at the time of prescription of a +2.00D. sph. add.⁸ Some jobs will demand a shift to trifocals before a +2.00D. sph. add is needed.

Visual skills vary with age. This is widely appreciated so far as near acuity is concerned; but investigation shows interesting trends in other functions, too. Figure 3 shows the relationship between distance acuity and age for over 7,000 employees in a steel mill. The upper and lower curves enclose the middle 50 percent of the acuity scores made at each

age. Since these curves are practically parallel it is obvious that the spread of scores changes little with age. Hence, the conclusion can be drawn that loss of acuity with age is universal. As a result, industry is beginning to recognize that a satisfactory level of employee visual acuity today may be unsatisfactory later and that employee job performance may be affected by this change with age. Likewise, industry is becoming aware of the fact that those employees who use spectacles for constant wear or for near use are, in general, better in job performance (figs. 4 and 5). Therefore, it can be expected that periodic rechecking will be encouraged among the employees.

Some jobs such as dyeing, paint mixing, color printing, wiring of electrical devices with colored insulation wire, the sorting of colored plastic products, and the like, require the skill of good color discrimination. Simple tests for the detection of color blindness are coming into use in industry; but this is not enough. What is needed is a simple means of evaluating the "color-normal" worker's capacity for hue discrimination, for this varies considerably from individual to individual quite apart from ability or inability to identify and name colors properly. Two workers may both pass color-blindness tests with perfect scores, and yet differ greatly in ability to discriminate close-together shades of red or close-together mixtures of yellow and green. And, there is evidence that this ability changes with age.⁹ Methods of testing color discrimination are being studied and developed, and will eventually be made available to industry in the form of simple instruments or additions to present test-batteries.

There are many jobs that demand some degree of stereopsis for best performance. Among some that might be mentioned are truck operation, assembling, and inspec-

tion on small parts. Depth perception changes with age, too, but does not decline steadily. Rather, in most cases, this skill increases up to about age 30, remains fairly stationary until approximately age 50, then declines rapidly (fig. 6). One explanation for the increase in stereoptic acuity from age 20 to 30 is that experience in work requiring perception of depth improves this function. This explanation has been advanced independently by Snell and Kuhn. Tiffin¹⁰ concludes that this ex-

Fig. 6 (Lueck). Relation between age and stereoptic acuity. From Tiffin, "Industrial psychology," p. 152.

planation implies that an increased ability to perceive depth may be accelerated through training.

Adaptation to some jobs changes visual skills. Particularly is this true of near-point applications such as inspection and assembly operations on small parts and close-tolerance manufacturing operations. By way of comparison we might look at the distribution of near-acuity scores for groups with less than six months' experience versus groups with over six months' experience in radio-tube assembly (fig. 7). Tiffin and Wirt⁵ suggest that there are at least two possible causes for this difference: Only persons with exceptionally good near acuity will stay on the job; or, acuity improves on the job. Some 26 percent of the employees in the senior group wore glasses; but 20 percent had glasses in the junior group,

which does not suggest that the higher acuity in one group was due to any greater use of professional eye care and optical aids.

Another near-point task, hosiery loop-

Fig. 7 (Lueck). Relation between near acuity and experience on the job for radio-tube assemblers. From Tiffin and Wirt.⁵

ing, also causes shifts in skills with tenure on the job. Figure 8 shows the relation between the number of employees passing a distance-acuity test and experience on the job. There is a very substantial downward trend in distance acuity which manifests itself whether or not glasses are worn. This might be expected as the result of continued work at the extremely close distance of 8 inches neces-

sary to obtain an enlarged image of the work so that it can be seen adequately. The actual change in focus posture was measured and is shown in figure 9. These people became "occupational myopes."

Of interest to management and the safety engineer are relationships between visual skills and accident rate. Unfortunately, the accident may not have happened to the particular employee whose poor vision was the cause, and the statistical approach to this problem is not easy, since adequate records are difficult

Fig. 9 (Lueck). Relation between focus posture and experience on the job of hosiery looping. From Tiffin, "Industrial psychology," p. 154.

to obtain. The breaking of a defective machine part may injure a workman through no fault of his. The blame should lie with the inspector—usually in some

sum of far and near heterophorias. From this curve we ascertain that those with the *least* change in convergence effort from distance to near show the greatest accident rate; those with the *greatest* change in convergence effort from far to near show the lowest accident rate. This observation relates directly to the changes in convergence that occur with changes in stimulus to accommodation, which, in turn, are affected by the lenses prescribed.

Another study¹¹ compared visual skills as found in injury-free groups with visual

piston-ring inspectors and from the application to them of the previously mentioned battery of 12 visual tests by means of the Ortho-Rater, a precision Brewster-type haploscope.

Figure 11 is a reproduction of the summary sheet of scores made by all the people in the department, on each of the 12 visual tests administered. Scores for right and left eye have been deleted to avoid the confusion of many numbers, since neither the right nor the left eye is specifically important on this job.[†] A record of the scores for the poorer eye has, how-

skills as found in serious-injury groups and in groups showing high frequency of minor injuries. It was found that the injury-free group was significantly superior to the serious-injury group in acuity of the poorer eye at near. The injury-free group was also significantly superior to the high-frequency-of-minor-accident group in regard to lateral heterophoria at far and in depth perception.

Now that we have considered briefly the visual skills that have been found important in industry, some of the individual differences for various skills, their variation with age and with experience on the job, and their relation to accidents, it may be profitable to consider a specific group of workers. Let us see what statistical evidence has been developed from the ratings, on the job, of a group of 170

ever, been made. If this total group is broken up into the superior, good, fair, and poor operators according to their production or other performance rating on the job, and a summary sheet such as this is prepared for each sub-group, the arithmetical means of the scores for (say) acuity at near computed, and the means from sub-group to sub-group compared, the mean-acuity scores will show a progressive decrease from best to poorest employees (table 1). The findings of this

[†] It should be pointed out here, however, that on some jobs it is important to know whether the right or left eye has the better acuity. Job layout is often such that binocular vision of the work is prevented by the hand or by some object in the line of sight of one eye. This peculiarity is disclosed by close inspection and also by the correlation of right- or left-eye vision with job performance as revealed by testing.

particular test, then, are related to performance on this job.

If, for each score, the percentage of superior and good operators is computed, a practical score limit at one or both ends of the scale is obvious. In this case, employees scoring below 10 are rarely good operators. If all the employees on this job were selected from among those who score 10 or better on binocular near acuity, the percentage of superior and good operators would be materially increased and the percentage of fair and poor operators materially decreased. The percentage change for the near-acuity visual standard adopted is also shown in table 1. The other visual skills significant on this job were likewise analyzed, of course, and a complete pattern of visual job requirements resulted. It was then possible to conclude that if every worker on this job had been able to meet these requirements, the output of the group would have been about 9 percent greater.*

The economic value of changes in this magnitude are very considerable in industry. Increases in production as small as 3 percent show a worthwhile saving on any substantial volume of production. For instance, a production increase of 3 percent on a \$3,000,000 yearly business would mean a saving of \$90,000.

One question that is certain to be raised relates to the employee who does not meet the visual job standards. What becomes of him? He is referred for professional attention and visual rehabilitation. We have no guarantee, however, that the rehabilitation will cause the employee to improve on the job. There may be other reasons for his failure. He may be better suited to some other work, and this will probably be disclosed in the careful consideration of his whole case. We do know that (other things being equal)

the man has a much better chance to make good on the job if his visual skills meet the job's requirements, and he will have a poor chance to make good if his visual skills do not meet job requirements. New employees should possess at least the minimal visual skills established as needed for the job.

It should be remembered that the entire battery of industrial-vision tests and the accompanying statistical fact-finding program for employee placement are not intended to "screen out" employees, and keep them from obtaining work. Different jobs have different visual demands. There are jobs in industry even for the blind. An industrial-vision employee-placement program permits the finding and establishment of visual-skill standards that will result in assignment of the better potential producers to a specific job. Other specific jobs have other visual requirements, and the employee not meeting one set may meet another and be put to work on the job for which he is best fitted visually. Further, these standards are flexible. They can be made more stringent in periods of plentiful labor and relaxed during periods of a tight labor market, with a full knowledge of attendant production changes that will occur. An employee-placement program based on known visual abilities will prove most satisfactory to both labor and management.

Rehabilitation of employees for any specific visual task has been mentioned, as has the specific peculiarity of the hyperphoria of the right eye found in milling-machine operators. The reader may have been wondering how he could know just what visual skills are required of any factory employee who is referred to him for eye care. One thing can be asserted: the employee will not be able to say how he uses his eyes. If questioned he may say that he operates such-and-such a ma-

* This information, as yet unpublished, was kindly furnished by Drs. Tiffin and Wirt.

chine. Pressed for more information, he will tell all about what the machine does—but not what he does, or how he uses his eyes. He will not be able to estimate at all exactly the working distances—ahead, to right, left, down, and up—that are imposed upon him, nor will he be able to estimate accurately what these distances should be. It becomes the clinician's problem to figure out these facts. This can be done in either of two ways. One can visit the plant and familiarize himself with the needs of the workers on each type of machine. When it is practical, this is the better method. Or, one can arrange with the plant's medical, person-

nel, or safety department to have the pertinent data furnished. This will usually be done as a matter of course as soon as the plant gets a visual fact-finding system underway.

Then, with the necessary data on the visual skills required and with the patient at hand, the problem is to try to give him comfortable working vision for the job, and yet allow him suitable vision for his life away from work. That is a problem which involves many considerations, principally in the relationships of accommodation, convergence, and visual acuity.

A VISUAL TEST FOR INFANTS

JOHN N. EVANS, M.D.

Brooklyn, New York

There are occasions in ophthalmic practice when it is desirable to demonstrate the visual efficiency of an infant. Although it is possible to make accurate eyeground studies and measurements of the refractive error and although the examiner may be able to form a general opinion satisfactory to himself, the parents are more satisfied if the ophthalmologist can actually demonstrate the child's ability to see.

The illiterate E symbol turned at different axes is often useful for this purpose in children of three years of age or older and occasionally in children somewhat younger. There is a wide gap between the newborn babe and the period when the illiterate E is useful. We are not taking full advantage of our opportunities in our study of visual response in this earliest age group. The device herein described gives ample support to this statement.

We have all seen these very small infants picking at minute specks on the coverlet and they seem particularly interested in small bugs or moving objects. In order to take advantage of this infantile curiosity, the test object as advocated for angioscotometry was quite successful in demonstrating the vision of these children. This minute white ball mounted upon a black stem is moved about against a black background. The idea of using minute dots for testing vision is, of course, not new. Grains of pollen were sometimes used in the days before Jaeger advocated type sizes.

It seemed more advantageous, however, to employ a means by which the examiner's hand would not appear in the field of the subject's vision, thereby distracting attention. To this end a small

tray (six inches by six inches with a one-inch rim) with replaceable white opaque plastic bottom was devised as a background for the test. The test objects themselves at present are iron filings. These are caused to move about on the

Fig. 1

white surface by manipulating a bar magnet* on the underside of the tray so that the only object in the infant's field of observation is the minute black speck (fig. 1).

It is obviously desirable to have a series of sizes of these objects and it seemed at first difficult to devise a satisfactory method of retaining the iron filings and at the same time keeping the various sizes separated. It was finally found practical

* The new and more powerful permanent magnets are available but the permanent magneprobe magnet is ideal.

to select appropriate sizes and stick them to strips of paper by means of mucilage. Each strip bears an appropriate number indicating the size of the filing as measured with a micrometer.* When objects larger than 0.5 mm. are desirable, it is possible to use steel ball bearings which can be purchased in graduated sizes. One can then test the child with gradually increasing sized objects until its attention is attracted by the movement.

The infant is held on the mother's lap facing the examiner. A uniform illumination is caused to fall upon the tray from above and behind the subject so that no shadows may distract the child's attention. A few preliminary tests may be run and the mother may participate in order to gain the infant's full coöperation. When the child's interest has been once aroused, the mother covers one eye with her hand and the examiner then watches for the child's interest to develop. When an amblyopic eye is covered, the child's interest is maximum. When, however, the "good eye" is covered and the amblyopic eye is exposed, the child will endeavor to remove the mother's hand in order to pursue the minute speck. It is this reaction on the part of the infant which insures the dependability of the test even more than the child's unsuccessful efforts to find or follow the movements of the filings.

Should the child succeed in getting one of these specks into its mouth, the minute iron filing or even ball bearing, would not in any way injure its mouth or digestive organs.

Those cases in which the child does not respond (as with congenital cataracts, or other developmental defects) to the largest-size ball bearing, an increase in the intensity of the stimulus may be ob-

tained by applying the ophthalmoscope stem with its mounted pinhole cap applied directly to the underside of the translucent tray bottom. A sharply defined and measurable light disc is projected through the bottom. Its intensity can be varied by adjusting the rheostat† and its size can be modified by using caps of varying-size apertures. The spot is caused to move about on the surface of the tray so that the child's attention is held and its responses noted in the same way as when the iron filings or ball bearings are used. The tray may be held vertically so that the examiner can look over its edge in order to be sure the movements of the child's eyes coincide with those of the illuminated spot.

The illustration will supply an adequate idea of the construction and application of the device.

It is, of course, obvious that in any event the test does not measure visual acuity but rather a condition of responses to brightness, contrast, and movement. Contact has been made with a number of ball-bearing manufacturers. They are unable to supply more than samples until the war is over. The smallest sample thus far supplied measures 1/64 inch in diameter. Smaller sizes are desirable—about 1/100 of an inch will probably be about right. Only one size object will be necessary, as additions of one or more follow the movements of the magnet as one.

After examining a number of hundred infants with iron filings and comparing the results of the examinations, the writer concludes that many children as young as three months old give reliable responses to the movement of the iron filings (table 1). No effort has been made to tabulate the results as it has been impossible to

* It is, of course, not possible to secure filings of exactly uniform size.

† Variations of intensity are to be avoided when possible as they are not measurable and involve color change.

TABLE 1
RESPONSE TO VISUAL TEST FOR INFANTS

Age	Stimulus	Nature of response	Responding percentage	Assumption	Remarks	Authority
Term*	Intrusive reflex	Aimless wandering	100		Movements not greater than 35°. Horizontal only.† Not continuous.‡ No family history of squint	A
First 10 mins.	Flashlight	Lid reflex	100	Retina functioning	Pupils react. About 1 per 1000 have brown iris irrespective of color or race	B B
During first 10 days	Flashlight	Transient convergence reflex	9	Macula begins to function	Same as above	B
5-6 weeks	Flashlight or massive objects	Follows movements with eyes for few seconds	100 ?	Developing macula function and muscle coordination	Approach of nurse or mother more frequently noted	A
6-8 weeks	Smaller objects	Follows movements for few seconds	100 ?	Same as above		A
3-4 mos.	1" black cube against white surface at 2'	Follows movements for 1/2 minute	100 ?	Visual acuity 6/728.00	Head moves. Also inspects own hands. †Crude as an actual measurement	A
6 mos.	1 3/4" black cube against white surface at 2'	Follows movements through full angle of eye movements	100 ?	Visual acuity about 6/288.00	†Method of testing can be improved. Has perceived red and yellow for about three months	A and C
9 mos. to 1 yr.	Black cubes on white	Follows with eyes. Hands and body in prolonged attention.	100 ?	Development and coordination of all eye functions. Visual acuity about 6/72		A
2 yrs.	E chart	Indicating position of letter	100 ?†	6/12		A
3 yrs.	E chart	Indicating position of letter	100 ?†	6/12		A
4 yrs.	E chart	Indicating position of letter	100 ?	6/9		A
5 yrs.	E chart	Indicating position of letter	100 ?	6/6		A
6 yrs.	Snellen	Reads	100 ?	6/6	From this point on less liable to develop strabismus	A

* It has been pointed out that if a powerful light be flashed on the abdominal wall of a pregnant woman shortly before term, fetal movements will become more active. This may not be an ocular response at all. The writer does not believe that this is 100 per cent, however.

† Inserted by J.N.E.

‡ In my experience only 50 percent of children two years of age will respond.

? Percentage questioned by the writer.

REPEATABILITY OF KERATOMETRIC READINGS*

ROBERT E. BANNON, B.S., AND RITA WALSH, B.S.
Hanover, New Hampshire

INTRODUCTION

The reliability of the various measurements made in the determination of ocular anomalies is a question that arises occasionally. Opportunities for determining the accuracy or repeatability of ophthalmic instrumentation are infrequent. The time and cost to the patient and to the examiner are factors that often outweigh the other values of studies of this kind. Nevertheless, it is important that the reliability of the instruments and techniques used be known. The final result of any examination will be influenced by the reliability of the instruments and techniques used; this in turn necessarily depends on the stability of the conditions being measured and on the possible variations in measurement due to the interpretation of the examiner.

With respect to the keratometer two of these factors—namely, the reliability of the instrument and the effect of the examiner's interpretation—are determined in this study.

The stability of corneal curvatures in nonpathologic cases is generally accepted. The role which ophthalmometry should play in the determination of the total ametropia has been discussed innumerable times and need not be considered here. In the presentation of the data, however, the subjective refractive corrections are included for the interest that they may have for some readers.

Few studies dealing with the repeatability of ophthalmic instrumentation can be found in the literature. For example,

*From the Clinical Division of the Dartmouth Eye Institute, Dartmouth Medical School.

the repeatability of the ophthalmo-eikonometer measurements was reported¹ in 1940. This study included also the repeatability of the refractive error as determined by the method of stigmatoscopy.

The nature and statistical frequency of astigmatic errors have been recently studied in the prescriptions given to 2,000 consecutive patients at the Dartmouth Eye Institute. Astigmatic corrections below 0.25D. cyl. were not considered. The results of the study are given in the following table:

TABLE 1
DISTRIBUTION OF ASTIGMATIC ERRORS

Type of Astigmatism	Number of Patients	Percentage
With the rule	631	31
Against the rule	412	21
Oblique (axis 20° off the horizontal or vertical)	562	28
With the rule in one eye and against the rule in the other eye	57	3
No astigmatism or astigmatism below 0.25D.	338	17
Total	2000	100

From this table it is seen that 83 percent of the patients had astigmatic errors of 0.25D. cyl. or more, whereas the astigmatism of the remaining patients was considered insignificant.

It is obvious from the high prevalence of astigmatic errors in routine refractive cases that all refractionists should be aware of the reliability of the instruments and methods used to detect astigmatism. Since the cornea constitutes four fifths of the total refracting power of the eye, the measurement of the curvature of this surface determines the main seat of as-

tigmatism. Aside from regular refractive cases it is helpful in cataract surgery to know the corneal curvatures before and after the operation. The surgeon may be guided in the type of operation when he has found by keratometric readings that certain techniques result in more post-operative astigmatism than do others. The use of the keratometer in aniseikonic examinations enables one to calculate ^{2,3} the expected meridional image-size difference and, in the case of oblique astigmatism, the declination error. In contact-lens fitting, in cases of amblyopia, in cases of suspected malingering, and in cases of corneal pathologic change the keratometric measurements provide objective data of value which, as this study shows, may be relied upon as being accurate and affected to only an insignificant extent by the personal error. This paper reports a study of the reliability of the keratometric or ophthalmometric measurements.

METHOD

A comparative study was made of the cases in which two keratometric measurements had been taken on the same patients* within a period of less than six months. A period of less than six months was impractical because only a few patients returned within a shorter period. Measurements on 50 unselected patients are reported, entailing 200 readings on 100 eyes. Despite the small number of cases used in this study, the results are so definite that it seems justifiable to present them at this time. The measurements were taken by six different examiners, but the majority of the readings were made by only two. The keratometers used were those made by the American Optical Company, by the Bausch and Lomb Opti-

cal Company, and by Carl Zeiss, Inc.; however, most of the measurements were taken on one instrument.

DATA

The data on 100 eyes are given in the following table (table 2.). The age of the patient, the repeated keratometric readings, the subjective refraction, the instrument used, and the initial of the examiner are included in the table.

The average age of the 50 patients included in this study was 32 years, the range being 8 years to 60. The average amount of corneal astigmatism measured in the 100 eyes was 1.32D; the range was from 0 to 5.25D. The average amount of subjective astigmatism for the 100 eyes was 1.09D.; the range was from 0 to 5.00D.

In the following tables (3 and 4), the differences in amount and axis of the corneal astigmatism between the repeated readings are summarized.

The maximum difference in the amount of the corneal astigmatism determined by the repeated readings was 0.75D.; the average difference in amount was 0.14D. In 68 percent of the cases the difference in amount was 0.12D. or less. In 92 percent the difference in amount was 0.25D. or less. This indicates that although a few deviations may be relatively large (the maximum being 0.75D.) most of the differences between repeated readings are very small (less than 0.25D.).

The maximum difference in axes between repeated readings was 15° but the average difference was only 3°. In 66 percent of the cases the variations in axes were 3° or less. In 87 percent of the cases the variations were 5° or less. These average deviations in amount and axis between repeated readings are very small.

An attempt was made to find a relation-

* None of the patients included had any corneal pathologic change or corneal irregularities.

* For each case, the first two readings are for the right eye and the second set of two readings is for the left eye. The readings in the primary and secondary meridians are given and these meridians are noted by the figures following the slanted (/) line.

ship between the absolute amount of corneal astigmatism measured and the repeatability of the readings. The 34 cases in which there was no difference in amount between the repeated readings averaged 1.36D. of corneal astigmatism. The eight patients who had a maximum difference between readings (0.37D. or more) averaged 1.38D. of corneal astigmatism. That is, the amount of astigmatism measured was essentially the same in these two categories and was also substantially the same as the grand average of amount (1.32D. cyl.) of astigmatism for the 100 eyes. The repeatability of keratometric readings relative to the

TABLE 3

REPEATABILITY OF KERATOMETRIC READINGS AS TO AMOUNT

0.37	5	97
0.50	2	99
0.62	0	99
0.75	1	100

amount of astigmatism measured, is therefore independent of the total amount of astigmatism.

A similar attempt was made to find the relationship between the repeatability of axis determinations and the absolute amount of astigmatism measured. The results are given in table 5.

Since the axis position in seven cases of spherical corneas was indeterminate, these cases were excluded from this distribution. It is apparent from a study of the table that the lower the amount of corneal astigmatism the less repeatable are the axis determinations.

In analyzing the results by examiners and instruments the data have been classified into three groups:

TABLE 4

REPEATABILITY OF KERATOMETRIC READINGS AS TO AXIS

eyes were taken by a combination of the six examiners; that is, either both repeated reading were taken by examiners E, H, M, or T, or one reading was taken by one of the six

* Examiners B and W had an instrument of type B in their refracting rooms and therefore used it consistently.

examiners and the other readings by another examiner. In this last category the readings were taken with either one of the three instruments: A, B, C.

The results of this analysis are summarized in table 6.

TABLE 6
ANALYSIS OF RESULTS BY EXAMINERS AND INSTRUMENTS

Examiner	Number of Eyes	Instrument	Average Deviation
B	36	B	0.09
W	38	B	0.14
All	26	All	0.20

The average deviations between repeated readings varied in the different categories from the total average deviation (0.14D.) by ± 0.06 D. There was a small variation between the readings taken by different examiners on the same instrument, indicating that the variations are not due to the different instruments. One can conclude, therefore, that keratometric readings are influenced only to a very small degree by the discriminative ability of the examiner.

It was thought that the slight variations in repeated readings were due to involuntary movements of the patients' eyes. Therefore, repeated readings were taken on an artificial (glass) cornea* having an astigmatism of 1.62D., which was rigidly mounted before the keratometer. The repeatability of successive readings taken by examiners B and W on the glass cornea showed variations similar in amount and in axis to those found on human subjects. This would indicate that movements on the part of the patients did not account for the variations found in this study.

* We are indebted to F. W. Jobe of the Bausch & Lomb Optical Company, who kindly loaned us the glass cornea and attachments for mounting it before the keratometer.

SUMMARY AND CONCLUSIONS

1. The analysis of repeatability tests on the keratometer indicates that these readings are quite repeatable in determining the amount and axis of the corneal astigmatism.

2. In rare cases the difference in amount between repeated keratometric measurements may be relatively high. In this study of 100 eyes there was one case with a difference between repeated readings of 0.75D. In the majority of cases (92 percent) the deviation was 0.25D. or less.

3. Similarly, in a few cases the difference in axes between repeated keratometric readings was as high as 15° , but in the majority of cases (87 percent) the difference was 5° or less.

4. No relationship was found between the total amount of corneal astigmatism and the repeatability of the amount of the readings.

5. On the other hand, there was a definite relationship between the total amount of corneal astigmatism and the repeatability of the axis readings. That is, the higher the amount of corneal astigmatism the more dependable were the axis determinations.

6. This study of the repeatability of keratometric readings on 100 eyes indicates that the keratometer is a reliable instrument for the measurement of corneal curvatures and that the importance of the interpretation of individual examiners is negligible. The stability of the corneal curvatures is verified by the constancy of repeated readings.

7. The role of the keratometric readings in the eventual diagnosis and therapy, although difficult to analyze, is important because one can be guided by the accuracy and consistency of corneal curvatures and interpret changes in subjective refraction in terms of factors other than the cornea.

Significant differences in subjective refraction not substantiated by changes in corneal curvature must indicate lenticular or indicial changes. This information may be of diagnostic value.

8. Since the cornea constitutes four fifths of the refracting power of the eye, since its front surface can be *accurately*

measured by the keratometer, and since changes or lack of changes in its curvature may have diagnostic importance, it seems worthwhile to recommend the keratometer as an important adjunct to the battery of instruments and techniques used in refractive measurements.

NOTES, CASES, INSTRUMENTS

A CASE OF MULTIPLE TUBERCULOUS NODULES OF THE EPISCLERA*

BERNARD KRONENBERG, M.D.
New York

Episcleritis and scleritis of a tuberculous origin are rare diseases. American literature does not contain many reports of these lesions; most of them are to be found in the foreign literature.

The question as to whether these lesions, which are nodular in appearance, are scleral or episcleral frequently cannot be answered. The site of origin is most probably in the episcleral tissue, and as the nodule increases in size, it begins to involve the conjunctiva and the outer and middle layers of the sclera. There are many transitional forms, which can involve the sclera alone or the episcleral tissue to a lesser or greater degree. Many investigators believe that in cases of deep tuberculous scleritis there must be uveal involvement. Pollack¹ has reported a case of an isolated tubercle of the sclera without involvement of the uvea. Many of the German authors write of tuberculous conjunctivitis and episcleritis, because of their feeling that the two cannot be separated.

The question as to whether these nodules are primary tuberculous infections or secondary in nature has been discussed at length by Schieck,² Junius,³ Davids,⁴ and others. Schieck, in considering the mode of origin of tuberculosis of the conjunctiva and episclera, came to the following conclusions on the basis of the work of Ranke and Igersheimer⁵: (1)

*From the Eye Service of the Gouverneur Hospital. Presented before the New York Society for Clinical Ophthalmology, on February 5, 1945.

That the tubercle bacillus can penetrate the conjunctiva without causing a lesion in it. (2) That the diagnosis of primary tuberculosis of the conjunctiva requires a swelling of the regional lymph nodes. (3) That those cases of tuberculosis of the episclera without such swelling must be considered endogenous or secondary in nature.

Most other authors believe these lesions to be secondary in nature. Krückmann⁶ also stated that tuberculosis of the eye is rarely associated with tuberculosis of the lung, but is frequently associated with tuberculosis of the thorax and abdomen. It is a well-known fact that in tuberculosis sanatoria, where patients with active lung lesions are found, there are exceptionally few cases of ocular tuberculosis.

Most reports in the literature deal with individual tuberculous nodules; Duke-Elder⁷ noted several nodules forming intermittently; and Schultz⁸ has reported a case of multiple nodules of the conjunctiva and episclera. The last named writer excised one of the nodules and found it to be typical tuberculous granulation tissue, but no tubercle bacilli were found. In this case the nodules became confluent and then ulcerated. The entire area was then covered with connective tissue. The patient showed old corneal opacities of both eyes. X-ray studies of the chest showed a tuberculous lesion on the right side.

In determining the differential diagnosis, the following conditions must be considered:

1. Phlyctenular conjunctivitis. This is distinguished by a nodule in the conjunctiva which is surrounded by conjunctival vessels. It is not painful on palpation and is associated with some form of dietary deficiency.

2. Episcleritis associated with rheuma-

toid arthritis, the lesions of which are single with a superficial vascularization usually near the limbus. The patient complains of pain, photophobia, and lacrimation. There is a history of rheumatoid arthritis.

3. Anterior scleritis is a diffuse swelling of the anterior segment of the globe, more extensive than the nodules of episcleritis. Several nodular areas fuse, until in the worst cases the inflammation extends entirely around the cornea to form an annular scleritis.

4. Lymphoma of the conjunctiva is characterized by a transparent edematous mass which is not nodular in appearance. It occurs in the subconjunctival tissue and is frequently associated with hyperplasia of the lymphoid and blood-forming tissues.

5. Gelatinous or brawny scleritis is a diffuse swelling of the sclera which may hang down over the cornea. It has a gelatinous and succulent appearance. Eventually it infiltrates the cornea and opacifies it. It is frequently associated with more or less severe uveitis.

The case reported here is one of multiple tuberculous nodules of the episclera and sclera.

Fig. 1 (Kronenberg). Multiple tuberculous nodules of the episclera.

Fig. 2 (Kronenberg). Photomicrograph of section through a tuberculous nodule. $\times 125$.

D. K., a white woman, aged 64 years, had noticed in April, 1944, that the upper part of the right eye was inflamed and painful. There was no photophobia, and no discharge (fig. 1). At the age of 3 years both eyes had been inflamed after an attack of measles. Her general condition at present (blood pressure, urinalysis, and Wassermann test) were within normal limits. The chest, however, gave evidence of an active tuberculous lesion in the left upper lobe of the lung.

Ocular findings: Vision O.D. was 20/100; O.S., 20/400. The conjunctiva below was clear. In the area involved there was an edema of the conjunctiva with dilation and engorgement of the conjunctival vessels. Under the conjunctiva there were several small yellowish nodules.

The cornea of the right eye, centrally, presented an old opacity, localized under the epithelium. At the 4- and the 2-o'clock positions there were infiltrates extending from the limbus for 2 mm., with conjunctival vessels going to them. In the left eye also a central large opacity was localized under the epithelium, but contained

no vessels. Nasally there were some vessels going from the limbus.

The fundi were not clearly observable.

One of the nodules was excised and the pathologic report as given by Dr. A. Sala follows:

"The lesion consists of a central mass of necrotic tissue, caseous material, and fragments of nuclei here and there. This central debris is surrounded by some epithelioid cells and lymphocytes. One or two giant cells are to be seen. The histologic diagnosis is tuberculosis. Stains for tubercle bacilli were negative, but the histologic examination is characteristic of a tuberculous lesion" (fig. 2).

At present the patient is beginning to show signs of a thinning of the sclera in the area involved and exhibiting the char-

acteristic bluish color. She is receiving tuberculin therapy.

This case is reported because of the following unusual features:

1. There are few reports of multiple nodules of this nature.

2. Its association with an active lung lesion demonstrates the fact that it is metastatic in nature. This adds to the evidence that is accumulating that these lesions are secondary in nature.

3. A biopsy specimen was obtained so that the diagnosis of a tuberculous lesion could be established on a histologic basis.

4. This case demonstrates that deep tubercular scleritis can occur without involvement of the uvea.

A TENDON-TRANSPLANTATION TECHNIQUE FOR EXTERNAL- RECTUS PARALYSIS*

FRANK C. LUTMAN, M.D.†
Rochester, New York

Because of the medial origin of both the superior and inferior recti, and because of the attachment of a part of their tendons nasal to the vertical meridian of the eyeball; a subsidiary function of these muscles is internal rotation. In external-

rectus paralysis, transplantation of the whole of the vertical-rectus tendons to a position temporal to the median vertical plane largely converts the internal rotation of these muscles into the more desirable action of external rotation. O'Connor¹ has achieved this in three ways: (1) by laying the inner halves of the vertical-rectus tendons over the lateral halves; (2) by transplanting the whole; or (3) by transplanting the inner halves of the vertical-rectus tendons to the corresponding borders of the external rectus.

The following technique is also a successful means of applying this principle to external-rectus paralysis (fig. 1). The

*From the Department of Surgery, The University of Rochester School of Medicine and Dentistry and the Strong Memorial Hospital.

†Now Lt. (MC), A.U.S.

external rectus is resected but not immediately reattached to the sclera. Through the same conjunctival incision the vertical-rectus muscles are exposed one at a time. Their tendons are split in the middle with a sharp hook, and the muscle is divided back for an additional 10 mm. with scissors. The outer muscle slip thus formed is transplanted to the sclera behind the insertion of the external-rectus muscle. The inner muscle slip is transplanted to the position previously occupied by the outer muscle slip. The resected external rectus is replaced to its original attachment. Most cases of external-rectus paralysis are not treated surgically until complicated by some degree of internal-rectus contracture. A recession upon this muscle can usually be done to advantage.

The vertical recti can be split back as far as possible without injury to their innervation because the nerves enter these muscles at the junction of the posterior and middle thirds. The transplanted muscle slips ride smoothly across the sclera without excessive tension. By means of the new attachment of the vertical recti, a strong action of external rotation opposes the internal rectus.

Case 1. A girl, aged nine years, had congenital bilateral external-rectus paralysis and a 30-degree left internal strabismus. Vision: R.E. 6/7.5-3; L.E. 6/12-1.

A strong left internal rectus was recessed 5.5 mm. The external rectus was resected 6 mm. The outer three fifths of the vertical recti were transplanted to a point behind the insertion of the external rectus; the nasal tendon slips were moved to the outermost insertions of the vertical recti. Postoperatively, 14 degrees of right hypertropia and 20 degrees of exotropia existed. The left eye could be rotated 48 degrees externally. Two months after the

first operation, the left internal rectus was advanced 5 mm. I did not see this patient again, but when seen in the same clinic two months following the last operation, she was reported to have 6 degrees of exophoria and some right hyperphoria. Internal rotation for the left eye was 40

Fig. 1 (Lutman). Tendon transplantation technique for external-rectus paralysis.

degrees and external rotation 35 degrees.

Case 2. A girl, aged 17 years, was semi-comatose for a week following a motorcycle accident in June, 1943. Skull X-ray studies at the time revealed no fracture. Upon regaining consciousness the patient had no sensation on the left side of her face, and her left eye was nearly blind. She could not rotate the right eye externally to the midline. Nine months after the accident, when I first saw her, the left side of her face was hyperesthetic. No tears were shed from either eye when she "cried." Vision was: R.E. 6/7.5+3; L.E. the perception of fingers at one foot. The optic disc of the left eye was chalky white from primary atrophy. The patient's head was constantly rotated far to the right. External rotation of the right eye was limited to 18 degrees nasal to the midline.

Ten months after the accident, with the patient under a general anesthesia, the right eye could be rotated outward with the aid of tissue forceps against a moderate amount of resistance from the contracted internal rectus. The internal rectus was recessed 4 mm. The external rectus was resected 5 mm. The outer halves of the vertical recti were transplanted to a

point behind the insertion of the external rectus. The inner halves of the vertical recti were transplanted to the normal attachment of the outer halves of these muscles. Postoperatively, the eyes were straight in the primary position without head rotation. The right eye could be rotated externally 23 degrees.

AN INSTRUMENT FOR TESTING DARK ADAPTATION

MR. E. W. GODDING presented a paper on this subject and described in various stages the apparatus used in measuring dark adaptation.

STUDIES IN DARK ADAPTATION IN THE DETECTION OF DEFICIENCY OF VITAMIN A

CAPTAIN JOHN YUDKIN, RAMC, presented a paper on this subject summarized as follows:

(1) If vitamin A affects any part of the dark-adaptation curve, it always affects the final rod threshold; other parts of the curve may or may not be affected. It follows that if only one point in the

curve is to be measured it should be the final rod threshold.

(2) In order to prove the existence of vitamin-A deficiency by measuring dark adaptation, it is necessary to apply the therapeutic test; that is, to see whether the dark adaptation is improved after the administration of the vitamin.

(3) Although the therapeutic test is essential in order to detect deficiency in an individual and desirable in groups, it is not always practicable to apply it to groups. In this case, presumptive evidence of deficiency may be obtained by comparing the dark adaptation of different groups.

(4) Since age affects dark adaptation, it is necessary either to allow for this in comparing groups of different ages or to compare groups of similar age.

Discussion. Dr. H. Pollak, Major R. E. Wright, Dr. W. D. Wright, Mr. D. V. Giri, Mr. F. A. Juler, Dr. Z. A. Leitner, Dr. H. S. Stannus, and Mr. E. W. Godding discussed this paper.

THE HERBERT IRIS-INCARCERATION METHOD OF OPERATION FOR GLAUCOMA

DR. MARY CRIPPS gave a demonstra-

tion of the visual fields before and after operation. She had used the Herbert iris-incarceration method in 306 cases, and the following were her conclusions as to the result.

I. Glaucoma with tension ranging from normal to 70 mm. Hg (Schiøtz)

In those cases of chronic glaucoma whether or not an acute or subacute attack has been superimposed on the chronic state, and if the tension varies from 25 mm. Hg to 70 mm. Hg (Schiøtz) and can be reduced (by appropriate methods) down to about normal, and if the field of vision varies from a sickle-shaped scotoma and peripheral depression (early stages) down to the more advanced stages of a restricted field and sloping-edged defects with depression of central vision—provided that not more than half of the fixation area within the 5-degree circle has been invaded—then the vision improves with the Herbert operation.

II. Glaucoma with tension above 70 mm. Hg

Included under this heading are those cases, whether suddenly acute or ordinarily chronic, wherein the tension has risen above 70 mm. Hg and can be reduced by intravenous glucose to normal limits but which rapidly rises again, and wherein the vision is reduced.

(a) In those cases wherein more than half of the fixation area has been invaded and there are doubtful areas of vision, the operation gives only relief from pain and tension, and the vision is liable to deteriorate.

(b) In those cases wherein vision is reduced to perception of light in the upper temporal quadrant the Herbert operation gives increased vision in this quadrant with reduction in tension to normal limits.

However, in these cases the operation must be modified, the edges of the incision are punched with a Lagrange punch be-

fore the fibrotic strands of the permanently dilated iris can be incarcerated.

Sclerosis of the lens which may exist in these cases of prolonged tension is inclined to increase but as soon as the sclerosis has progressed sufficiently the lens is easily removed because the gap in the iris already exists and the fibrosed iris tissue of the filtering scar lies deep to the cataract incision. The wound heals normally without subsequent increase of tension.

RETINIS CIRCINATA OF UNKNOWN ORIGIN IN A CHILD

MR. O. GAYER MORGAN presented an eight-year-old boy. His mother said he had complained of difficulty in reading. The vision was R.E. 6/18; L.E. 6/5. The fundus showed very marked retinitis circinata, with a small reddish or orange central spot which was just above the macula. The only relevant history was that he had had concussion a year previously, was bruised on the right side of his face, and the eye was closed. He was entirely healthy except that he suffered from asthma. He had a very large head, which might denote a mild degree of hydrocephalus, but it was a family trait to have large heads. His eye condition, presumably, was one of edema and hemorrhages, and it might have been considered a case of early Coats's disease; however, contraindications were that there were no engorged or large vessels, or angiomatous-looking enlargements, no deep swelling, and no detachment. It might have been a hemorrhagic condition as a result of the fall, but it was a little difficult to see how it could cause such retinitis circinata. It might have been one of those types of edema of the retina, usually unilateral, which occurs in children or young people for no apparent reason, and in which no actual cause of the process can be found. Mr. Morgan was anxious to know

whether anyone had seen anything like this before.

Discussion. Mr. Adams said that he presumed it might have been traumatic if, as a result of concussion, he had extensive choroidal hemorrhage with damage to the macula, the retinitis having developed subsequent to that.

QUESTIONABLE CONJUNCTIVAL EPITHELIOMA. QUESTIONABLE ATYPICAL MOOREN'S ULCER SUPERIMPOSED ON OLD MUSTARD-GAS DAMAGE

MR. ALAN HOLMES-SMITH presented a man, aged 60 years. There was a history of damage to the left eye by mustard gas in 1918. At that time he was hospitalized and treated for three months. During the past two or three months the lids of the left eye had become swollen. The swelling receded with the use of hot compresses. For three weeks prior to this examination there was ptosis of the left eyelid.

The vision was R.E. 6/24, L.E. ability to count fingers.

The right eye was normal on examination. The left eye showed an inactive pupil and no red reflex. The tension was normal. There was a firm raised area of conjunctiva below and medial to the limbus, extending into the lower fornix; the edge was raised. The lower nasal quadrant of the cornea was involved in the lesion, and an opaque area separated it from normal cornea. No enlarged glands were palpable in the neck.

Mr. Holmes-Smith said that there was some difference of opinion as to the diagnosis, whether it was an atypical Mooren's ulcer or a new growth. It was finally decided to enucleate the eye, and that was done completely with as much conjunctiva as could be taken from the lower fornix. On section the tumor was thought to be an epithelioma with considerable inflammatory reaction, with the sclera

undergoing invasion at the limbus. A course of radiotherapeutic treatment has been advised.

DR. MILTON L. BERLINER, *presiding*

✓ SYPHILITIC OPTIC ATROPHY AND TRYPARSAMIDE AMBLYOPIA

DR. H. HOUSTON MERRITT said that syphilitic optic atrophy may be secondary to meningeal involvement of the nerve or luetic chorioretinitis, but more frequently it is primary. Primary luetic optic atrophy may be the only manifestation of the disease, although more frequently it is seen with tabes dorsalis. The exact pathogenesis is not clearly elucidated but it is probably due to primary involvement of the nerve itself or its blood vessels by the disease. Spirochetes have been found pathologically in only two cases, both by Igersheimer. The characteristic visual defect consists of loss of central field with concentric or sector-shaped peripheral constriction. The course is progressively downhill and if one eye is involved the other may be expected to show the same condition within seven years. Useful vision may likewise be expected to be lost within seven years after the condition is recognized. Until recent years treatment has been ineffective, whether in the form of trivalent arsenicals, tryparsamide, or the Swift-Ellis method of arsenical treatment. Fever therapy is accepted today and if instituted sufficiently early, offers a 60-percent chance of arresting the condition. Penicillin has not been in use for a long enough period of time to determine its usefulness.

✓ Optic atrophy may be caused by tryparsamide. It is known that other pentavalent arsenicals have an affinity for the

optic nerve in experimental animals. It has been found that 8 percent of patients under tryparsamide treatment experience some visual phenomenon. In half of these patients this is purely subjective and not serious. A few hours after the injection the patient's vision is blurred for several hours by a shining mist, such as may be seen over a hot radiator. This will not recur if the tryparsamide is discontinued, but if the drug is continued blindness can develop with the fundus appearing normal. This blindness improves later with the return of central vision, but the visual field continues to be of a funnel type. Atrophy becomes detectable after several weeks. This visual disturbance usually occurs after the first few tryparsamide injections and is unusual, but possible, after the eighth injection.

Although it has been claimed that the tryparsamide does not directly induce the blindness but lights up syphilis already in the eye, the great speed of the appearance of the blindness (three hours) indicates that the drug itself is at fault. Also, there have been cases of blindness after tryparsamide administration to nonsyphilitic individuals. When tryparsamide is administered there are three safeguards against these complications: (1) ophthalmoscopic and visual-field examinations are performed to weed out abnormal cases, as these show 10 times the frequency of the complications; (2) only small doses should be administered at first; and (3) be on the alert for subjective symptoms.

Discussion. Dr. James W. Smith thought that Dr. Merritt stressed a point of practical importance regarding the poor visual prognosis in tabes either with or without therapy. If the inexperienced ophthalmologist fails to recognize this, he will be blamed by the patient for authorizing a therapy that induced blindness. Close coöperation is essential between the syphilologist and eye physician before

therapy with tryparsamide is started. Unfortunately, in some cases wherein there is vision and field loss other systemic disease may contraindicate fever therapy. Unless penicillin is proved effective against cerebrospinal syphilis, the doctor will still be confronted with a dilemma.

Dr. Merritt thanked Dr. Smith for re-emphasizing the importance of close co-operation between the ophthalmologist and syphilologist in the treatment of these cases of optic atrophy. Although some claim that all patients with syphilitic optic atrophy will be blind within seven years, he said that he did not believe that this was necessarily true. It is probable that some cases come to a spontaneous arrest. He did not believe justified the feeling of some ophthalmologists and syphilologists that tryparsamide can be used in the treatment of patients with optic atrophy. At the present time fever treatment is the method of choice. When using tryparsamide in the treatment of neurosyphilis, one should be very careful to watch for the development of visual symptoms, as it is a powerful and dangerous weapon.

INVOLVEMENT OF THE OCULAR SYSTEM IN DEMYELINATING DISEASES

DR. ARMANDO FERRARO presented a table summarizing the most important manifestations of involvement of the ocular system in various types of demyelinating diseases; such as multiple sclerosis, diffuse sclerosis, Schilder's disease, Devic's disease, Baló's disease, Krabbe's disease, and so forth.

He attempted to establish that from the clinical as well as the pathologic standpoint, all these various supposedly clinico-pathologic entities are nothing else but variants of the same fundamental process of demyelination of the central nervous system, in relation to age at onset, resistance of the individual, and virulence of the pathogenic factor.

He attempted further to make a comparison between the most important features of the histopathologic process of the various demyelinating diseases with the main features of allergic reaction of the brain. The material for such a comparison came from the Department of Neuropathology of the New York State Psychiatric Institute where since 1940 Dr. Ferraro, first in collaboration with Jervis, and then with the Kopeloffs, investigated the reaction of the nervous tissue to experimental allergy. Briefly, the essential features of experimental allergy, such as demyelination, vascular infiltration—first with polymorphonuclear cells and then with lymphocytes and histiocytes—reactive pliosis, presence of edema, occasional hemorrhages, presence of granulomatous-like formation with giant cells, occasional thrombi of small blood vessels, and occasional endarteritis, are all features which may be found in the so-called demyelinating diseases.

Dr. Ferraro drew the conclusion that the pathology of the demyelinating diseases including the pathology of the ocular system may be viewed also in the light of an allergic reaction.

Discussion. Dr. Daniel Kravitz said that ophthalmologists are dismayed by the large number of names which describe apparently similar conditions. The situation is analogous to the practice of attaching names to every corneal spot which appears somewhat different from the others. Regarding the possible allergic basis for the causation of the demyelinating diseases, Dr. Kravitz believed it too great a simplification. Here again one is reminded of the variety of ocular conditions explained by some as due to a single cause, vasoconstriction. Allergy as a cause for the demyelinating diseases does not explain the large number of familial cases in which patients reach a certain station in life and then are attacked by these diseases.

TOPICAL DIAGNOSIS OF DISTURBED OCULOMOTOR MOTILITY

DR. ALFRED KESTENBAUM differentiated between types of palsy of muscles supplied by the oculomotor nerve:

(1) Nuclear type: The arrangement of the centers for the individual eye muscles in the third-nerve nucleus is still controversial but it is more or less accepted that the cranial (superior) part represents the homolateral levator and superior rectus. Below these centers is the center for the inferior oblique of the same side. The inferior part of the nucleus and the neighboring trochlear nucleus represent the contralateral inferior rectus and superior oblique, respectively, and their fibers must cross the midline. The medial rectus is represented in the medial parts of both oculomotor nuclei. Briefly, the elevators have their centers homolaterally, the depressors contralaterally, and the medial rectus bilaterally. Owing to this complex arrangement a single focus in the nucleus cannot involve all the muscles supplied by the oculomotor nerve of one eye, and complete oculomotor palsy of one eye excludes a nuclear lesion. Partial oculomotor palsy is more frequent if the lesion is nuclear than if it is subnuclear. Bilateral paresis of single muscles indicates a nuclear lesion.

(2) Dorsal fascicular type: A lesion here, usually accompanied by involvement of the nucleus ruber or of the substantia nigra, shows also a disturbance of the tonus, muscular coördination, and sometimes sensibility of the opposite half of the body. This corresponds to the old "Benedict's syndrome," oculomotor palsy, and crossed hemitremor.

(3A) Ventral fascicle type: Here a lesion is usually associated with a pyramidal-tract lesion in the pes pedunculi, resulting in Weber's syndrome, oculomotor palsy, and crossed hemiplegia.

(3B) Root type: A lesion of the root

of the third nerve, after it leaves the brain stem at the medial side of the peduncle, also results in a Weber's syndrome, which therefore is ambiguous, being due to a lesion in the brainstem or one in the interpeduncular region.

(4) Basal type: After leaving the brainstem, the third nerve passes forward in the subarachnoid space at the base of the brain, first mesial, then below the peduncle, and then between the posterior cerebral artery and the superior cerebellar artery for a total of 2 cm. before perforating the arachnoid and dura to enter the extradural space. In its "basal" portion the nerve may be damaged by basal meningitis, a tumor, or especially an aneurysm of one of the aforementioned arteries. This type of oculomotor palsy may be monosymptomatic and its topical diagnosis very difficult. A Wassermann test and arteriography, which is not harmless, may aid localization.

(5) and (6) Posterior and anterior cavernous-sinus types: From the point of penetration of the dura until it reaches the superior orbital fissure, the nerve runs within the wall of the cavernous sinus. In addition to the oculomotor palsy, there may be signs of a lesion of the cavernous sinus and involvement of the neighboring fourth, fifth, and sixth nerves. The first and second branches of the trigeminal may be involved only in the posterior cavernous-sinus type of lesion, whereas in the more anterior lesions only the first branch of the fifth nerve is implicated; while a thrombosis of the cavernous sinus and an arteriovenous aneurysm of the carotid artery without venous communication may be symptomless except for the palsy and therefore resemble the basal type of lesion.

(7) Orbital-fissure type: Here the third, fourth, fifth, and sixth nerves are involved, but there are no signs of a cavernous-sinus lesion.

(8) Orbital apex type: A lesion in the apex of the orbit presents signs of third-, fourth-, fifth-, and sixth-nerve disease and also optic-nerve involvement, with central scotoma progressing to blindness, temporal pallor becoming optic atrophy, and, if the lesion takes space, exophthalmos is also present.

(9) Muscular type: The previously mentioned types of third-nerve palsy must be differentiated from lesions in the muscles themselves, as occurring in the nerve endings in myasthenia gravis, or with orbital tumors. In the muscular type of lesions either all or part of the extraocular muscles are involved, and in the latter case the muscles are involved independently of their innervation. For example, a tumor above the eye may involve the superior rectus and oblique muscles, which are innervated by different nerves.

(10) Neuritis type: Neuritis, or other processes restricted to the nerve itself; as in diabetes, infections, intoxications, may produce monosymptomatic oculomotor palsy which may be confused with the basal type.

Discussion. Dr. Percy Fridenberg pointed out that a very early symptom of fifth-nerve involvement in orbital-apex and fissure lesions is silent and must be elicited. This is anesthesia of the frontal branch, missed by most ophthalmologists, but later becoming a severe neuralgia.

Dr. Kestenbaum stated that the diagnosis of anesthesia of the trigeminus cannot be based upon the loss of the corneal reflex alone, but all regions supplied by the nerve must be tested. X-ray studies are of great importance in topical diagnosis but were not discussed. It should be emphasized that the final diagnosis is made by the neurologist; that the ophthalmologist can only interpret the ocular sign to further his purpose.

Secretary.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

January 8, 1945

DR. T. F. LEATHERWOOD, *presiding*

SYMPATHETIC OPHTHALMITIS FOLLOWING IRIDENCELEISIS

DR. RALPH O. RYCHENER reported a case of sympathetic ophthalmitis with loss of vision in both eyes following iridencleisis for simple glaucoma. Mrs. I. H., aged 64 years, was seen on June 4, 1943, for a routine eye examination. She had no complaints other than an occasional blurring of vision in the right eye and burning and itching of both eyes. The vision was R.E. 6/7.5, improved to 6/6 with $- .50D.$ sph.; L.E. 6/20, improved to 6/6 partly with $+1.00D.$ sph. $\approx +.25D.$ cyl. ax. 90° . The addition of a $+2.50D.$ sph. enabled her to read Jaeger 1 with each eye.

Ophthalmoscopic examination disclosed some lens haze and glaucomatous cupping of the disc of the right eye. Lens haze was present in the left eye and the disc was normal. The tension was R.E. 37 mm., L.E. 25 mm. Hg (Schiotz). There was slight concentric contraction of the visual field of the right eye. The patient was given 1-percent solution of pilocarpine for use in the right eye four times daily and was seen rather frequently until October 26, 1943, during which time the right eye became more myopic, visual acuity decreased to 6/7.5, partly, with correction, and the tension could not be controlled by other miotics. Operation was advised, and on November 1, 1943, iridencleisis was performed on the right eye. There were no surgical difficulties of any kind, convalescence was uneventful, and the tension remained below 20 mm. until December 6th, when she

returned with the left eye red and painful, and the vision diminished to 6/24. Plastic iritis was present in both eyes, and, although posterior synechiae were present, the iris responded well to the instillation of epinephrine-bitartrate crystals.

The patient was hospitalized and given foreign proteins and aspirin in large amounts and made some progress. During this time she developed atropine dermatitis and obtained general toxic symptoms from scopolamine ointment, 0.5-percent.

On January 4th new vessels had appeared on the iris of the right eye so as to give the impression of rubeosis. Two infected, unerupted milk teeth were removed, further foreign-protein therapy was administered, plus pilocarpine sweats and glucose intravenously for cyclic vomiting, but the inflammatory changes progressed until hyalitis, uveal cataract, and angular synechiae with diminution of vision to light perception presented the final picture of the end result of sympathetic ophthalmitis.

Enucleation of the right eye was performed on April 6, 1944, because of intractable pain. Following is the report of the microscopic examination by Col. J. E. Ash of the Army Medical Museum:

Microscopic: There is a scar of a perforating wound of the cornea at the limbus. There appears to be a coloboma of the iris on this side but the rest of the iris and the ciliary body are greatly thickened by a massive granulomatous inflammatory process which also involves the scar and adjacent conjunctiva. Areas of necrosis in the conjunctiva, which appear to have reached the point of caseation, are surrounded by radiating epithelioid cells. There is pigment in and around these tuberclelike lesions and around one of them are giant cells which contain refractile foreign bodies. There is no evidence of caseation in the intra-

ocular granulomas in which the epithelioid and giant cells frequently contain pigment granules. There is diffuse lymphocytic and plasma-cell infiltration of the entire uveal tract. In the choroid this is particularly dense in the outer layers, whereas in the ciliary body it is the inner layers which are particularly involved. The retina shows lymphocytic periphlebitis but is comparatively uninvolved. There are inflammatory pupillary and cyclitic membranes. Serofibrinous exudate occupies the anterior chamber and there is serous exudate in the ciliary body, choroid, sub-retinal space, and vitreous chamber. The retina is detached. The lens has undergone degenerative changes. Because of the uveal distribution of the granulomatous process, intraocularly, we believe this is a case of sympathetic ophthalmia in spite of the caseation and foreign-body reaction in the conjunctiva. We should, however, like to know the condition of this eye before iridencleisis and the present condition of the other eye."

SYMPATHETIC OPHTHALMITIS

DR. RALPH O. RYCHENER reported a case of sympathetic ophthalmitis following an injury to the right eye and resultant involvement of the left eye after 44 days. M. C., aged 27 years, struck in the right eye by a broken log chain on December 2, 1944, was attended by Dr. Stanford Herron, who removed the prolapsed iris and ciliary body and sutured the laceration of the sclera. Vision in the left eye remained 6/6 until the forty-fourth day following the injury, when the left eye began to be painful and the vision failed very suddenly.

The patient was seen in consultation on the forty-ninth day, when the visual acuity in the injured eye was 3/60 and in the sympathizing eye 1/60. Since it was possible that the injured eye might prove

ultimately to be the better eye, enucleation was delayed while active treatment with foreign protein in the form of diphtheria antitoxin, autohemotherapy, and local treatment was instituted. Recurrent anterior-chamber hemorrhages occurred in the right eye, and nine days later this eye was removed.

Pathologic examination disclosed incarceration of the ciliary processes and pigment in the scar of the penetrating wound at the limbus; the lymphocytic infiltration and foci of epithelioid cells indicative of sympathetic ophthalmia were present.

Despite saturation with sodium salicylate, extraction of infected teeth, and all other recommended forms of treatment, the left eye deteriorated to the plastic uveitis which is the end stage of sympathetic ophthalmia. The vision was perception of moving objects only, and the tension was 40 mm. Hg. (Schiøtz):

CYCLODIATHERMY

DR. RALPH O. RYCHENER reported a case of compensated glaucoma in a colored man treated with cyclodiathermy after previous iridectomy. W. A. W., aged 28 years, was seen September 29, 1943, with normal vision in each eye. The tension in the right eye was normal; in the left eye it varied from 48 to 56 mm. Hg (Schiøtz), with a typical glaucomatous field. The tension in the right eye was never recorded as greater than 30 mm. Hg, and the visual field in this eye was normal.

On January 28, 1944, following a congestive attack in the right eye which yielded to paracentesis, a broad-based iridectomy was performed. Despite miotics, the tension steadily rose to 48 mm., and on February 26th a cyclodiathermy with both the Weve tip and micropin was performed across the lower quadrant.

There was marked reaction, the eye became very soft, with much choroidal edema and hemorrhage into both the choroid and retina over the treated area. Visual acuity was reduced to perception of moving objects. Under the administration of atropine and "mixed treatment" internally, there was gradual recovery, and on January 8, 1945, the visual acuity was 20/25, tension was 13 mm., and the fundus was entirely free of hemorrhage and showed only a few chorioretinal scars over the affected area. It was apparent that in this case a lesser application of diathermy current would have produced a good result, since it is undesirable in such cases to induce an iridocyclitis of this degree.

KERATITIS SICCA

DR. RALPH O. RYCHENER reported on Mrs. W. W. B., aged 65 years, who was afflicted with arthritis deformans and complained of ocular discomfort and of burning and itching associated with aropy conjunctival discharge for which she had received much local treatment without relief.

She was seen for the first time on September 11, 1942, at which time there was a diffuse staining of the cornea, with much epithelial debris adhering to the cornea. The Schirmer test showed a wetting of the filter paper of $2\frac{1}{2}$ mm. after five minutes. Locke's solution and holocaine ointment were prescribed, and the Beetham operation advised. This surgical advice was disregarded until June 4, 1943, when all four puncta were sealed off with an actual cautery, and Feldman's solution was prescribed.

There was instant relief of all symptoms and the patient's only complaint after a year was that her eyes were now too moist. It might seem advisable to perform further operations for this condition in two stages, sealing off the lower

puncta first and repeating the procedure above if it seems necessary.

GLAUCOMA

DR. E. C. ELLETT reported a series of cases of glaucoma.

Case 1. Miss M. was seen in 1916, with chronic simple glaucoma. The vision was normal. The discs showed cupping and the visual fields were contracted. The vision failed some in that year and a Lagrange operation was performed on the left eye in November, 1916, and on the right eye in October, 1920. In December, 1944, 28 and 24 years after the operations, respectively, for left and right eyes, the tension was R.E. 19, L.E. 23 mm. Hg (Schiøtz). The visual fields showed some contraction but had remained stationary from 1934 to 1944. Cataracts developed and the lens was removed from the right eye in December, 1944, a combined intracapsular operation being done. The patient was feeble and senile, but the eye had done well.

Case 2. Mrs. J., aged 45 years, had been under observation since she was 9 years old. She wore the following correction: R.E. +5.50D. sph.; L.E. +4.50D. sph., with satisfactory results. In 1921 she had had an acute choroiditis in the right eye which healed with a pigmented scar above the macula. The vision was reduced to 20/40. In 1935 she had an attack of acute glaucoma in the right eye, for which a trephining with complete iridectomy was done. The tension remained very slightly elevated in the right eye. The vision was normal for distance, but defective for near, with an almost complete ring scotoma which included the blind spot. In November, 1944, vision with glasses was R.E. 6/7.5, partly; L.E. 6/6. There was cupping of the disc in the right eye. The left was normal. The tension was 35 mm. Hg (Schiøtz)

in each eye. Eserine did not control the tension, so mecholyl and prostigmine were used. The tension fell to 25 mm. in the right eye, but rose to 60 mm. in the left eye, with pain and some blurring of vision. The tension was relieved by pilocarpine, heat, and morphine, and in two days was 19 mm. The patient was advised to continue using pilocarpine.

Cases 3 and 4. J. R. and S. R., identical twins, aged 48 years, had been under observation for chronic glaucoma for several years.

J. R. was seen in 1916 for a soft movable tumor of the conjunctiva of the right eye. This was removed and reported as a hemangioma. The eyes were otherwise normal. In 1940 a diagnosis of glaucoma was made, and he was given treatment by a doctor in Texas. In 1942 the tension was R.E. 26, L.E. 22 mm. Hg (Schiotz). In 1944 the vision was still normal, with correction for myopic astigmatism. The fundus was normal in each eye. The tension was 32 and 28 mm. The visual fields were normal.

S. R. was seen for the first time in 1931. He also had myopic astigmatism. He had had Buerger's disease for three years, but the eyes were normal. When seen in 1940 the right eye was normal. The left eye showed some lens opacities, a cupped disc, and the tension was 52 mm. In 1944 the left eye showed no change, but the tension of the right eye was 41 mm. The vision was normal in the right eye. In the left eye the cataract had matured, and the vision was reduced to light perception. Since there was a history of trauma to the left eye in childhood it was considered possible that there was a connection between this and the present condition, although in 1931 the vision had been normal, but there were some peripheral lens opacities. Operation was advised on the right eye.

Case 5. Mr. A. H., aged 60 years, was seen for the first time in 1937, when a diagnosis of glaucoma was made. The left eye had been weak as the result of a railroad accident in which he had suffered the loss of an arm and acquired the morphine habit. The corrected vision was 6/7.5 and 6/9. The fundi were normal. The tension was R.E. 24 mm., L.E. 19 mm. Hg (Schiotz). Visual fields were normal. The condition remained about the same until March, 1944, when he had an acute attack of glaucoma in the right eye, with the tension 54 mm. Both irides were slightly atrophic. He would not permit a paracentesis to be performed. In October the right eye was operated on in another city. When seen in December he had a blind and painful eye, but it was impossible to tell what had been done. The left eye was quiet. The tension was 46 mm. There were many small keratitic precipitates on Descemet's membrane. The right eye was enucleated. Treatment with miotics, all of them except doryl, had not reduced the tension in the left eye, which remained around 50 mm. The eye was not painful, the fundus was normal, and vision was 6/12. The visual fields were almost normal. Repeated paracenteses gave only temporary reduction of tension. The iris showed some atrophy and visible vessels. The cornea had cleared somewhat, but was not free of precipitates. On January 6th, a cyclodiathermy with paracentesis was done. The lower half of the eye was treated with contact diathermy and current of 35, exactly as described by Drs. Albaugh and Dunphy. The tension on January 8th was 25 mm.

KERATOCONJUNCTIVITIS SICCA

DR. J. WESLEY MCKINNEY reported the case of Mrs. C. F., aged 39 years, who was seen on June 10, 1942. She complained of redness, burning, discharge,

and photophobia of several years' duration. For the preceding three months the vision had become so blurred at times that she could not read the newspaper. A complete physical examination revealed only a slightly lowered basal metabolic rate and a low-grade anemia. She had received many local treatments of silver nitrate and had taken vitamins, iron, and thyroid for an extended period of time. Examination revealed that the palpebral conjunctiva was red and thickened and had a ropy secretion. There was slight circumcorneal injection and epithelial keratitis with many filaments. The eyes were internally normal and the tension was normal. The vision was R.E. 20/50, L.E. 20/30, with correction. Schirmer test revealed the litmus paper to be wet only 3 mm. in 5 minutes. She was given Locke's solution which improved her condition partially, but she was still so uncomfortable that she readily accepted the suggestion for obliteration of the puncta. Consequently, all four puncta were obliterated by means of the diathermy needle. Relief was almost immediate. The conjunctiva and cornea rapidly returned to normal, the vision to 20/20 in each eye. She was able to read with comfort for the first time in several years.

CHRONIC BLEPHAROCONJUNCTIVITIS DUE TO LID WARTS

DR. J. WESLEY MCKINNEY reported the case of Mr. A. M. E., aged 57 years, who was seen for the first time on October 12, 1942. He had received much local treatment for chronic blepharoconjunctivitis of the right eye, all the local medications having been applied without benefit until two small marginal lid warts were removed from the upper lid. Following the removal of the warts, the blepharoconjunctivitis cleared rapidly and there had been no return of the

condition. It is supposed that this conjunctivitis resulted from the virus infection associated with the warts.

UVEITIS WITH ALOPECIA, POLIOSIS, VITILIGO, AND DYSACOUSIA—REPORT OF TWO CASES

DR. G. K. KAMBARA, by invitation, said that Vogt first described the syndrome wherein uveitis was associated with alopecia, vitiligo, poliosis, and dysacusia in 1906. Later a larger series was reported by Koyanagi and Harada from Japan. Depigmentation of the lashes had been reported associated with iritis as far back as 1873 by Schenkl and in 1874 by Jacobi. Association with vitiligo was reported by Gilbert in 1910.

This disease occurs most frequently in the third decade of life. The uveitis is usually bilateral and of an exudative type. It is slowly progressive. The process seems to be self-limiting with good vision maintained in about 30 percent of the cases; however, more frequently, there is permanent loss of vision. The fundus picture is one of edematous retinitis and choroiditis.

The alopecia and the poliosis of hair, eyebrows, and lashes occur in 90 percent of the cases. Vitiligo and dysacusia occur in 50 percent. Occasionally there are signs of meningeal irritation.

Nothing definite is known as to the etiology. An endocrine origin was postulated by Koyanagi, but Duke-Elder thinks more of the toxic origin. Treatment is symptomatic. Any operative procedure is usually unsuccessful.

The two patients whose cases are reported below did not show dysacusia. Both did complain of arthritis, however.

Case 1. A colored woman, aged 36 years, was seen for the first time in the Eye Clinic of the Memphis E.E.N.T. Hospital on May 23, 1943. She com-

plained of a painful left eye since having a tooth extracted in September, 1942. The vision was R.E. 20/20-2, L.E. 20/65. Examination revealed keratitic precipitates and posterior synechiae. A diagnosis of acute iritis was made, and heat and atropine were prescribed. Two milk injections were given, with some improvement of the patient. One month later papillitis was noted in the left eye. Kline test was negative. On August 18, 1943, a tonsillectomy was performed because of recurring sore throats and earache of several weeks' duration. From July to November the patient did not return to the Eye Clinic. When she did return she had seclusion and occlusion of both pupils but no iris bombé. There were still ciliary injection and many keratitic precipitates. Tuberculin tests of 1:10 and 1:100 dilution were negative. She complained of pain in her knees. Another general medical examination was advised. In December, 1943, tuberculin treatment was started with 1 mm. of 1:100,000 tuberculin. A course of typhoid antigen starting with 10 million organisms was also given for five doses. No appreciable improvement was noted. An iridectomy was performed with difficulty on January 28, 1944. The iris was very adherent and atrophic. In one month's time the iridectomy area was covered again. Tuberculin treatment was again instituted, starting this time with 1:2,000 dilution. In April, a course of X-ray treatments was given to both eyes at the John Gaston Hospital. Following this the eyes were more painful. In May there were numerous nodules on the iris and hypopyon was also present. By July, 1944, more and more new vessels were appearing on the iris, hypopyon was still present, and the patient showed local reaction to the tuberculin. The tuberculin was discontinued.

In August, 1944, she had the remaining

teeth extracted and felt improved. When she returned in October she showed depigmentation around the lids. The lashes had turned gray. She had developed alopecia and poliosis in the hair of the parietal region. The cornea of the right eye had turned opaque. Her condition was shown on slides.

Case 2. A Japanese woman, aged 46 years, was seen in the Tule Lake WRA Hospital in September with a complaint of painful eyes for several months. Examination at that time revealed ciliary injection, keratitic precipitates, and areas of posterior synechiae. Attempts at dilatation of the pupil with adrenalin and atropine were not very successful. She was given a course of typhoid-"H"-antigen foreign-protein therapy with only slight improvement. While in the Hospital she complained of headaches, and joint pains as well as ocular pains. All her teeth were extracted. With each extraction she suffered a flare-up in her eyes. Sulfadiazine by mouth was given for about two days, without appreciable effect. The synechiae increased until she had total seclusion and occlusion. Several weeks after the typhoid treatments, her hair started to fall out in spots and the remaining hair became gray and coarse. She was seen by an ophthalmologist from Stanford University and Klamath Falls on different occasions. A second course of typhoid was given about two months later. A few months later vitiligo was noted around the neck and face. Then still later her lashes started to turn white. During the time under observation from September, 1942, until June, 1943, her eyes became progressively worse. She had pain and ciliary injection when last seen. She had no hearing impairment. Wassermann and tuberculin tests were negative.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois*; Society Proceedings to *Dr. Donald J. Lyle, 904 Carew Tower, Cincinnati 2, Ohio*. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 E. Wisconsin Ave., Milwaukee 2, Wisconsin*.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

DR. HAESSLER EDITS THE ABSTRACT DEPARTMENT

The Abstract Department of the American Journal of Ophthalmology has occupied a distinctive position in the journalism of the specialty. The Germans were pioneers in the attempt to present to their readers a comprehensive summary of the periodical literature of ophthalmology. Other abstract departments than that of Theodore Axenfeld in the *Klinische Monatsblätter für Augenheilkunde* and that presented by the American Journal of Ophthalmology for the past nineteen years have usually made very

little pretense at completeness, and most of them have represented simply a sort of space "filler."

More systematic annual review of the periodical literature of ophthalmology was attempted in the German *Jahresbericht*, whose date of publication was, however, usually a year or two behind the original dates of publication of the material which it surveyed.

Edward Jackson undertook, at first inadequately, later more comprehensively, to gather the world's ophthalmic literature in a single publication, the *Ophthalmic Year Book*, appearing soon after pub-

lication of the original material. When, in 1926, on account of financial and other difficulties encountered, Jackson decided that it was necessary to discontinue the Ophthalmic Year Book, the present writer proposed an attempt to furnish a fairly sufficient substitute for the Year Book in the form of an abstract department which should at least approach completeness of presentation of the world's current ophthalmic literature.

There can hardly be any question that such a department is of value to the general reader, and of much greater value to those who have occasion to carry on literary research; although it must be acknowledged that many subscribers to medical periodicals find little time for thorough reading.

Successive labors on the Ophthalmic Year Book, on the general editorship of the Journal, and in the conduct of the Abstract Department have occupied a substantial share of the present writer's time for the past thirty-five years. Such tasks bring many rewards in the sense of service to the profession, in contact with the best of the world's medical literature, and in delightful and stimulating personal associations. But it does not seem unreasonable to seek leisure in the evening time of life. The writer, therefore, with mingled regret and satisfaction, yields the editorship of the Abstract Department to other hands. Beginning with the current issue, the Department will be edited by Dr. F. Herbert Haessler, who was a collaborator on the Ophthalmic Year Book and who for many years has furnished some of the best material of the Abstract Department. The present writer, who greatly values Dr. Haessler's willingness to devote himself to this task, wishes him success, and at the same time cordially thanks the many willing helpers who by their labors have made the Abstract

Department possible.

(The writer feels that this message to our readers would not be complete without sincere acknowledgment of the earnest and capable service rendered in this work for many years by his secretary, Miss Grace M. Carter.)

W. H. Crisp.

AMERICAN OPHTHALMOLOGICAL SOCIETY MEETING

The eighty-first annual meeting of the American Ophthalmological Society was held on November 12th, 13th, 14th at the Homestead, Hot Springs, Virginia. This is an unusual time of year for this meeting which is regularly held at the end of May or the first part of June each year. It had, however, been voted to omit the 1945 gathering because of the war. With the cessation of hostilities the Council decided to hold a belated meeting because of papers previously prepared and in order not to interrupt annual meetings which had been held every year for 80 years.

There was question in the minds of the officers as to the likelihood of good attendance, owing to the relatively unfavorable time of year and the difficulties of transportation. Much to their surprise, however, the gathering was the largest this Society has ever held. The weather, too, smiled on the meeting and the first two days were warm and sunshiny. The third day, however, was raining and ended in light snow.

First, of course, should be mentioned the scientific program, not only because, however pleasant the social aspects, the primary purpose of this Society is now and always has been scientific. From its meetings have emanated many outstanding contributions to ophthalmology. This meeting was no exception. In fact, many of the

members and guests stated that it was one of the best programs that they had ever heard. Space will not permit more than mention of a few of the subjects discussed. But a word might be said about some especially interesting items.

No one could ask for a clearer exposition of some physiologic factors in the differential diagnosis in the superior rectus and superior oblique paralyses than that given by Adler. The illustrations and diagrams were almost sufficient without the clear discussion by the author. Bedell showed beautiful colored photographs of retinal proliferation in diabetes. The listener can always count on seeing the most beautiful examples of fundus photography whenever Dr. Bedell presents a paper of which the subject can be so illustrated. Ruedemann showed examples from a series of over 100 plastic eye implants in all types of sockets. The prosthesis is placed inside of the muscle cone and the recti muscles are attached to it through appropriately placed holes in the material. Undue reaction does not follow the operation and obviously splendid motion is obtained. Surprisingly the conjunctiva takes care of itself satisfactorily without suturing to the acrylic implant. The technique is difficult and probably improvements will be found. But the procedure seems worthy of careful study. Samuels presented beautiful slides of pathologic eyes illustrating cataract and intraocular tumors. His specimens were, as usual, always of the highest order.

Beautiful illustrations of keratoplasty were shown by Castroviejo, and a catalogue of suitable types for this procedure and those better suited to keratectomy were outlined. This classification should be useful to those whose experience is limited.

Gundersen, one of the few members still in service, presented evidence from

19 Vossius rings that the iris margin has nothing to do with their formation, their size being practically the same irrespective of the hour of day or night that the injury took place. He thought also that the deposit could scarcely be due to attached iris pigment and likened it further to the central disc seen in capsular exfoliation and somewhat similar to arrangements of deposits in the anterior capsule in chronic intraocular inflammation. In general, his conclusion was that some fundamental characteristics of the lens capsule were probably responsible for the formation of the ring.

Kirby made some important points regarding ptosis and pseudoptosis. His talk indicated the necessity of careful differentiation between the two as a preliminary to possible surgery and a knowledge of whether the superior rectus was truly paralyzed or not.

Berens showed interesting statistics on the relative value of nylon; plain and chromic catgut, and silk, especially as concerned the coefficient of friction, post-operative reaction, and rate of absorption.

The meeting introduced two departures from custom, though not entirely unique features; namely, a reception for new members on the second day of the meeting followed by a banquet in honor of Dr. Vail, recently Colonel in the Medical Corps of the U. S. Army, Senior Consultant in Ophthalmology in the European theater, and Chief Consultant in Ophthalmology to the Surgeon General. The dinner was also in honor of Prof. Ida Mann of the Eye Hospital, Oxford, England, who has been visiting this country to study the eye institutions with a view to incorporating useful ideas into the construction of new eye hospital at Oxford and rebuilding the badly damaged structure at Moorfields. The presence of

Professor Mann with her equally delightful husband, Professor Gye, and her description of some phases of English ophthalmology at the dinner added much to the pleasure of the meeting. Dr. Vail gave a very interesting talk on his war experiences in ophthalmology. Among the most enjoyable features of the banquet were the delightful remarks of Dr. Beech, the President of the Society. His keen humor did much to enliven the evening.

Dr. Eugene M. Blake was elected president for the ensuing year and Dr. John W. Burke vice-president. Dr. John A. MacMillan was appointed the new council member and The Homestead chosen for the spring meeting unless the American Medical Association meets in the West, in which case plans may be changed to avoid unnecessary travel for those who desire to attend both meetings.

Lawrence T. Post.

THE NEED FOR MORE BASIC COURSES IN OPHTHALMOLOGY

The reestablishment of the basic course in ophthalmology at Northwestern University Medical School serves to call to our attention the crying need for the establishment of more similar courses as a precursor of residencies in ophthalmology. At the present time there are only three other courses of this type available: the one at the University of Pennsylvania, which is the oldest, one at Washington University in Saint Louis, and the one given by New York University.

The war has shown the need for more well-trained ophthalmologists in this country. From the number of applications received from returning veterans who are desirous of obtaining an adequate training in ophthalmology it is obvious that the needs can be filled if the training facilities are made available. At the pres-

ent time the opportunities are quite inadequate.

A three- or four-year residency in a well-established division of ophthalmology in one of the large university medical schools is probably the ideal way of obtaining a training in ophthalmology. Here, as part of the training, the basic sciences are taught by lecture and laboratory work. Here also are opportunities for work in the anatomy, special pathology, bacteriology, and research laboratories. The unusual library facilities also encourage study of the rare and most recently reported conditions. The association with the teachers of other branches of medicine tends to broaden the outlook and increase the knowledge of the relationship of other branches of medicine and ophthalmology. These opportunities are limited, as the number of residencies of this type is small. From this group must come our teachers, our research men, pathologists, and consultants. It is from this group that the teachers of the basic courses of shorter duration must also be obtained.

As already stated, the number of these regular residencies is entirely inadequate and not sufficient to fill the needs of the specialty. There are, however, many hospitals, especially larger county hospitals away from medical-school centers, that have competent clinical ophthalmologists who could and do teach clinical ophthalmology well. These men often have neither the time, inclination, background, nor the facilities properly to teach the basic sciences. For residents in such appointments the basic-science course as given by the four above-mentioned institutions is not only advisable but essential in the development of a "safe ophthalmologist." In these courses, of from 6 to 8 months' duration, the time is devoted to lectures, laboratory, and

clinical demonstrations. Thus in a relatively short time the foundation is laid for the future development of a dependable ophthalmologist. From personal observation it is apparent that the men who have followed up such a course with a year or two in some institution or clinic have done very well. It should be pointed out that this year of basic training must be followed by carefully supervised clinical work.

Unfortunately, because of the facilities required for such courses, the number of places available in these four established courses is limited and not sufficient to fill the needs. From the foregoing it is apparent that other facilities must be provided to make available to more men the proper teaching in the basic sciences of ophthalmology, which while not ideal would train them sufficiently well to qualify them for their American Board of Ophthalmology examinations; in other words, qualify them to be "safe ophthalmologists."

While less ideal than these methods of training the one suggested by Gradle warrants serious consideration. Gradle's suggestion is that a three-months' concentrated course in the basic sciences be given in a number of centers immediately following the general-interne year, and that the residencies start in October; that is, after the three-months' course. It would probably be advisable for a committee, perhaps representing the three major eye societies, to work out a uniform course of instruction that would cover the essential subjects and outline the methods of teaching to be used. This would permit the resident to devote three months to concentrated study without the care and responsibilities of a clinic, a great help if the resident had an appointment in an institution where one resident must shoulder the entire responsibility. In ad-

dition, the basic course would give him sufficient foundation to be of some help to the institution from the start. It would also have the tendency to encourage more institutions to resume the responsibility for the clinical training of men.

Training can also be obtained through preceptorship and association in private practice with a well-qualified and well-trained ophthalmologist. Here, especially, it is essential that the individual obtain his basic course before starting in practice, as the pressure of private practice is not conducive to theoretical instruction from the preceptor. However, having had the basic course and following it up with carefully planned reading, such as the Home Study Course of the American Academy of Ophthalmology and Otolaryngology, the young ophthalmologist is assured proper guidance in training.

It is hoped that American ophthalmologists, both teachers and clinicians, realize their responsibility and duty in the training of ophthalmologists and that more institutions establish basic courses as a precursor of residencies in ophthalmology.

Frederick C. Cordes.

BOOK NOTICE

ÉLÉMENTS DE GONIOSCOPIE NORMALE, PATHOLOGIQUE ET EXPÉRIMENTALE. By Archimede Busacca. Stiff paper covers, 200 pages, 81 illustrations including four plates, one in color. São Paulo, Brazil, Tipografia Rossolillo, 1945. Price not stated.

This book is an excellent statement of the author's personal study of the subject and of his conclusions; as well as a discussion of his own views and those of other writers with regard to many points in anatomy and diagnosis with regard to which differences of opinion exist. The

author suggests that, in the region dealt with, small differences of relief are of great importance, so that the region can be studied efficiently only by means of stereoscopic vision, the best conditions for examination being afforded when one applies to the study of the iridocorneal angle biomicroscopy as it is currently practiced for other parts of the eye. So keen were Salzmann's powers of observation, that Busacca believes other ophthalmologists, although provided with more perfect apparatus, have added little to Salzmann's observations as published in 1915, those observations having been made with the ophthalmoscope. The most satisfactory recent device for study of the chamber angle is that of Goldmann (*American Journal of Ophthalmology*, 1939, volume 32, page 444), who devised a contact glass furnished with a mirror in which the image of the angle is reflected.

A preliminary chapter on the technique of examination, using the Goldmann appliance, is followed by a chapter of general anatomic data on the chamber angle, and exhaustive chapters on the normal and pathologic angle.

In the chapter dealing with the pathologic angle, details dealt with include modifications of the angle following inflammatory processes of the uvea; gonioscopic aspects after operative interventions (iridectomy, cyclodialysis, incarceration of the iris); gonioscopy in diseases of the cornea; gonioscopic modifications in dislocation of the lens, in congenital deformities of the iris, and in glaucoma of various types. A note is added on the

zonule and the ciliary processes in gonioscopy.

A final chapter describes chiefly the author's personal experiments as to the modifications produced by atropine and eserine in the region of the chamber angle, particularly as regards the behavior of the ciliary body in iridectomized eyes. (Bibliography, 88 case records, index.)

W. H. Crisp.

CORRESPONDENCE

CONTINENTAL OPHTHALMOLOGISTS NEED OPHTHALMIC LITERATURE

Editor,

American Journal of Ophthalmology:

Since 1941, American publications have not been available to most of the Continental centers and investigators. I have had several letters from ophthalmologists abroad indicating the desire and need for ophthalmic literature which has appeared during these war years.

It occurred to me that some subscribers of the *American Journal of Ophthalmology* with copies for the past several years would be willing to send their copies abroad to ophthalmic centers or individuals. If such subscribers would write to the Howe Library of Ophthalmology, c/o Miss Jeanette Loessel, 243 Charles Street, Boston 14, Massachusetts, a name and address will be provided to which the *American Journal* may be sent. Arrangements are being made to reimburse the donors for the cost of mailing.

David G. Cogan, M.D.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

5

CONJUNCTIVA

Kadlicky, Roman. The chemotherapy of pyogenous conjunctivitis. *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 136-137.

Use of a sulfonamide (Dipron, which is 4 Aminobenzensulfonamide) by mouth has not only simplified the treatment of gonorrheal conjunctivitis of the new-born and adults, but is far superior to any previous method of treatment. F. Herbert Haessler.

Lewis, G. G. Ophthalmia neonatorum. *Med. Record*, 1945, v. 158, June, p. 351.

The author stresses the importance of ophthalmia-neonatorum blindness. In institutions 30 per cent of the blind had this condition. The organism involved may be gonococcus, pneumococcus, Koch-Weeks bacillus, staphylococcus aureus, bacillus coli, or other organism. The disease can invariably be prevented if proper prophylaxis is observed, and readily cured if early and proper treatment is instituted. Any per-

son engaged in midwifery should be strictly accountable for the proper care of the baby's eyes after delivery. The author gives his method of treatment, including frequent irrigation, silver-nitrate solution and, absolute cleanliness. Robert N. Shaffer.

Melik-Musian, B. N. The intravenous, subconjunctival, intramuscular, and subcutaneous use of sulfidine in trachoma. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 29.

On the basis of treatment of three hundred cases, intravenous administration has proved the most effective. Subconjunctival use proved too irritating and had to be abandoned. Intramuscular or subcutaneous administration works much more slowly, and is only used when intravenous administration is not practicable. Half-percent solutions, administered twice daily at an interval of 4 to 5 hours, 10 c.c. for the adult and 5 c.c. for the child, have been found adequate. In the presence of diplobacilli, zinc sulphate is used in ad-

dition, and follicles when massive are expressed. The results surpass those of all other treatments. A pannus crassus melts away under the method. Only five of the cases returned with relapses. The treatment is given during one month, at most. Usually patients are discharged cured in 20 to 25 days.

M. Davidson.

Volokitenko, A. E. The streptocide treatment of trachoma. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 32.

Complete cure was achieved in 60 percent of the thirty cases treated and improvement in the rest. Half of them had been in existence more than 2½ years, and all stages were represented. In some cases the effect was not noted immediately. Internal administration of 1 to 1.5 gm. per day was found adequate. Neither larger dosage nor addition of local use of the drug was found of any advantage. Effects were noticeable in less than two weeks.

M. Davidson.

Wolter, Friedrich. The occurrence of epidemic ophthalmia (kerato conjunctivitis nummularis epidemica) in Germany since 1938. *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 113-135.

In this 25-page analysis of epidemics of ophthalmia the author emphasizes the mode of occurrence of epidemics in order to clarify the factors that bring them about. Though he briefly describes the manifestations of the epidemics of eye disease which recently occurred in Germany and which seem to be identical with the shipyard epidemics in America, the theme of his work is the study of the process of epidemic morbidification. The epidemic of ophthalmia which occurred in Egypt in the period from 1798 to 1801 is particularly illuminating. The analysis of

this and other epidemics, the manifestations of which are well recorded, strengthens Wolter in his adherence to a view which he has previously published—namely that the epidemiologic concepts of Pettenkofer on the one hand and of Pasteur and Koch on the other are not irreconcilably antithetic. The older writer derived epidemic diseases from miasmatic, telluric, and meteorologic factors. The gaseous exhalations from the earth necessarily bound the epidemic to a certain area at a certain time. Careful analysis of the records of epidemics seems to confirm this belief. Ophthalmias that went through regiments of soldiers in Italy, for example, immediately ceased when the soldiers were transferred to France. The modern view ascribes the spread of the epidemic disease to the spread of the causative virus or bacterium. Nevertheless the facts that emerge from the study of the records of epidemics cannot be denied and the author emphasizes the importance of the study of the many neglected factors which are necessary to bring about dissemination of the immediate causative agent. Since the advent of the bacteriologic era only the latter has been considered, to the entire neglect of other indispensable factors which in prebacteriologic times were called miasma or contagium. CORNEA AND SCLERA

Chernikova, T. V. Sulfazol treatment of corneal ulcers. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 25.

Good results are reported from use of a 5-percent sulfazol ointment in 80 cases, among them 32 of *ulcus serpens*. Secondary iritis was noted in many and

is attributed to the toxic effect of the drug. M. Davidson.

Czukrász, Ida. **Scleral defects and their treatment.** Klin. M. f. Augenh., 1941, v. 107, Sept., pp. 245-257.

A report of 14 cases of defects of the sclera, operated upon according to the author's previously described procedure, namely covering the defect with combined conjunctival and Tenon's-capsule flaps. Nine cases were traumatic, two tuberculous, and three had developed scleral necrosis after Blascovics' strabismus operation (myectomy). (References.) F. Nelson.

Friede, Reinhard. **Causes, prevention, and treatment of opacities in keratoplastic grafts.** Klin. M. f. Augenh., 1941, v. 107, Nov., pp. 480-506.

The eyes of receiver and donor need careful preparation before transplantation. Tissue vitality has to be increased. The metabolism of the cornea needs improvement. The operation has to be performed with as little damage as possible to corneal tissue. Differences in thickness between the donor's and the receiver's cornea should be avoided. The graft should not be placed in any kind of fluid that could cause swelling of the tissue. If the anterior chamber of the receiver is shallow all remnants of exudate and blood should be removed, since their presence would lead to undesirable membrane formation. Grafts should be secured by cross sutures in every case.

To keep the graft from becoming opaque the author recommends the following rules: Abnormal swelling of the tissue should be treated before operation. Only donor eyes with normal osmotic pressure of the corneal parenchyma should be used. Epithelium and

endothelium should be normal in function. Grafts from eyes suffering from chronic or acute uveitis should not be used if other material is available. The graft, after being placed in the receiver's eye, needs attention and treatment at once, and carried through from two to three weeks. Even if the operated eye shows no irritation, prophylactic treatment of the patient, especially with foreign-protein injections, should start immediately in order to avoid irritation and exudation in the anterior segment of the eye. The author declares most emphatically that local and internal dehydration is of greatest importance to prevent undesired swelling of the corneal tissue and to increase the healing tendency. If shortly after transplantation the graft tends to become cloudy, Friede uses highly hypertonic solutions locally. Highly concentrated dextrose and leucose solutions are useful, but undissolved powdered sugar, put directly on the cornea and in the conjunctival sac, is even more effective. The author reports three cases of total corneal leucoma, operated upon successfully. The grafts became cloudy but cleared up again after general dehydration and local sugar applications. (7 figures.) F. Nelson.

Henderson, J. W., and Gillespie, D. R. **Unusual type of corneal opacities.** Amer. Jour. Ophth., 1945, v. 28, Nov., pp. 1236-1244.

Hofe, K. vom. **Clinical contribution to the understanding of keratitis neuroparalytica.** Klin. M. f. Augenh., 1941, v. 107, Aug., pp. 154-159.

Hofe describes the clinical course of corneal lesions in six patients in whom the Gasserian ganglion had been destroyed by electrocoagulation. Behr has described two forms of corneal dis-

turbance, namely central loss of epithelium in a round central area that heals with a dense scar and more extensive but also more benign punctate epithelial destruction which involves the entire corneal surface or at least its lower portion. In the author's patients both of the lesions occurred in the same eye at different times, and contrary to Behr's experience recurrences were not uncommon. Though the theory of trophoneurotic origin of these lesions has much support the author points out that in three of his patients the lesion followed trauma. In one of them there was evidence of physical trauma to the anesthetic eye, of which the patient was unaware. In the other two a loss of transparency of the epithelium such as is associated with chemical burns followed exposure to cold in one and contact with a drop of dilute alcohol in the other. (1 figure.)

F. Herbert Haessler.

Imre, Josef. **Clinical and histologic experience with corneal grafts.** *Klin. M. f. Augenh.*, 1942, Supplement 14, 50 pp.

To aid colleagues who have little practice in corneal grafting, Imre exhibits his accumulated experience. In the first 16 pages he describes in detail his operative procedure. He uses only grafts of living cornea, obtained by trephining from an eye just enucleated. The disc of clear cornea is inserted into a circular hole in the eye of the host, made by means of a Hippel automatic trephine. A safety collar surrounds the blade 1 mm. above the cutting edge. Only once has the writer injured a lens. The graft is immediately fitted into the opening, and a previously prepared conjunctival flap is sutured over the entire cornea.

In the remaining 34 pages Imre dis-

cusses his results. Of 98 eyes operated upon, the graft remained translucent in 56, and the visual acuity was improved in 42. In 31 cases the operation was performed on eyes such as are usually considered unsuitable for the operation, yet even so the statistics are encouraging. More than 20 eyes are discussed in detail and with colored photographs and some histologic illustrations. The beginner is advised to do his first few transplants on hopelessly defective eyes. (1 table, 64 illustrations, several in color.) F. Herbert Haessler.

Krasnov, M. L. **Albucid treatment of hypopyon keratitis.** *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 22.

A 30-percent aqueous solution or ointment has proved the best means of treatment of hypopyon keratitis. A ten-percent solution was not effective, nor was the stronger solution effective in scrofulous or herpetic ulcer. Frequent instillation is important, intravenous urotropine enhances the effect, and use of atropine locally is necessary. No case required surgical intervention, none went on to perforation, and only fine nebulae remained. M. Davidson.

Miklós, A. **Treatment of serpent ulcer by means of total covering with a conjunctival flap.** *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 138-154.

In the early stages of rather benign forms of serpent ulcer, energetic conservative treatment often brings about healing. In more serious forms none of the usual heroic methods of treatment—steam cauterization, trephine, paracentesis, splitting the base of the ulcer—has given so satisfactory results as conjunctival covering. Partial covering is inadequate, presumably because the adhesion between the entire ulcerated area and the conjunctival tissue de-

velops too slowly. Total covering is easily accomplished and should be preceded by curettement of the ulcer. It can be done in ambulatory patients. The author uses the technique described in the surgical treatise by Blaskovics and Kreiker. When healing is complete the adherent conjunctiva can be dissected from the cornea without difficulty. Results are most satisfactory. (13 illustrations, references.)

F. Herbert Haessler.

Radnót, Magda. The occurrence of corneal epithelium in the interior of the globe after ulcerous destruction in the cornea. *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 147-154.

The author describes histologic preparations from two eyes in which the epithelium had proliferated into the interior. The cause was not accidental or surgical trauma but ulcerative destruction of corneal tissue—a condition which has been rarely noticed before. In one of these eyes keratomalacia with destruction of the cornea was followed by iris prolapse and fistula. The corneal epithelium proliferated on the surface of the granulated tissue. In the other eye an epithelial cyst and an island of epithelial tissue developed within the eye after perforation resulting from gonorrheal inflammation in a new-born infant. The newly formed intraocular masses of epithelial tissue are separated from the cornea and iris by cicatricial tissue. (7 illustrations, references.) F. Herbert Haessler.

Salzer, Fritz. How do corneal defects become regenerated? *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 389-404.

A critical survey of the results of studies in comparative histology and embryology, as well as of tissue cultures, which all point in the same direc-

tion, makes it highly probable that the cornea is epithelial in origin, development, and regeneration. It must still be decided whether new corneal cells can be grown from stromal explants, remembering that differences in behavior of corneal cells may occur when they are stimulated in the explant by culture medium, embryonal juice or other trephone, and that in life they may remain passive because the epithelium does all that is necessary. Certainly there are no reasons for believing that a two-weeks-old mass which fills a corneal defect with cells morphologically and tinctorially indistinguishable from epithelial cells will be replaced later by proliferation of corneal cells. If contrary to expectation this should occur it would only show that in corneal regeneration all embryonic layers function together in an integrally organized process but that the epithelial functions are decisive in the pattern. (7 figures, bibliography.) F. Herbert Haessler.

Sato, Tutomu. Surgical method for keratoconus treatment (splitting of Descemet's membrane.) *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 234-238.

A special very small knife, curved at the end, is introduced into the anterior chamber through the limbus at the three and nine o'clock positions respectively, and Descemet's membrane as well as a good deal of the corneal parenchyma is incised from the rear in the horizontal meridian across the area of highest elevation of the keratoconus. The incision should be 3 to 5 mm. long. In case only a little of the corneal stroma is cut, one or two more cuts may be made parallel to the first one. Should the cornea be perforated during the operation, atropine is used in order to avoid anterior synechia. Otherwise

eserine is instilled. Immediately after the operation the internal corneal wound appears as a spindle-shaped cleft. The next day the vicinity of the wound is cloudy, and the stroma is swollen. Subsequently the thickness of the conical area of the cornea increases, and in the course of two or three months the conical shape disappears more or less, and the curvature approaches normal. Twenty-four eyes were operated upon, mostly with good results as to vision and shape of cornea. In many cases the myopia decreased considerably. (1 table, 6 figures.)

F. Nelson.

Schlichting, Hans. Vesicular endothelial dystrophy of the cornea. *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 425-435.

After a review of the literature on degenerative lesions of the posterior surface of the cornea, the author describes an observation of his own which concerns two cases of bilateral endothelial corneal dystrophy in father and daughter. The lesion involved the central area of the posterior corneal surfaces and consisted of round and oval vesicles and depressions of varying size. It is possible that the depressions were the end result of vesicles which protruded into the anterior chamber and had ruptured. The normal markings seen in specular reflection were partially obscured in the areas between the vesicles. Ophthalmometer readings suggested keratoconus, and certainly the myopia was corneal in origin because, when a contact glass with a curvature equal to that of the normal cornea was applied, retinoscopy revealed one diopter of hypermetropia. The difference between this lesion and similar ones recorded in the literature leads the author to conclude that this is a new

and unique observation. (2 figures, bibliography.) F. Herbert Haessler.

Zwiling, M. D. Scleromalacia perforans. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 36.

A case is reported accompanied by arthritis and macular degeneration, and located near the limbus, with atrophy of an adjacent iris sector, and cystic degeneration of the 7 by 3 mm. formation.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Bulach, K. O. The problem of early diagnosis of an "exciting" iridocyclitis. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 7.

The problem of potentially "exciting" uveitis in wartime is important. While 97 to 98 percent of enucleated eyes do not show the specific pathology suspected, the possibility alone justifies enucleation. With the object of verifying the studies of Rabinovich, which indicated the possibility of making an early diagnosis of the specificity of the uveitis by increase of blood monocytes, blood studies were made on 120 persons in whom one eye had been enucleated because of perforating injury. Only three showed specific pathology. The conclusion arrived at is that monocytosis is related to the acuteness and severity of the inflammatory process of the uvea rather than to its specificity.

M. Davidson.

Friedman, S. J. The prophylaxis, diagnosis, and treatment of sympathetic ophthalmia in the light of further observations. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 37.

Without a clear concept of its

genesis we have been handicapped in prevention and treatment of sympathetic ophthalmia. Until now we have been preoccupied with the mode of transmission from eye to eye and with the nature of the pathogenic agent. There is evidence in favor of a meningitic process mediating between the exciting eye and the sympathizing eye, and of the ocular affection not being limited to the eyes. The meningitic process is of the serous basal type with meager symptomatology, and the sympathetic ophthalmia responds to the same treatment to which basal meningitis responds, namely, spinal punctures. These therefore are indicated in all uveitides, and in the prevention of sympathetic ophthalmia. Two cases additional to those previously observed are reported in detail. Further arguments in favor of the relation between the meningitic process and sympathetic ophthalmia are advanced. The 2 or 3-weeks interval between the appearance of the process in one eye and its appearance in the other is similar to that observed in development of uveitis secondary to a virus in basal meningitis. The development of sympathetic ophthalmia after enucleation, sometimes 2 to 3 months later, and at times years later, argues for localization of the infectious process at the base of the brain. The occasional observation of optic neuritis in sympathetic ophthalmia is also in favor of a chiasmatic arachnoiditis. Both sympathetic ophthalmia and meningitis are more common in children, and the fact of sympathetic ophthalmia not being reproducible experimentally also speaks in favor of the belief. So far however no specificity of the spinal-fluid picture or specificity of the blood picture has been determined, nor has any marked difference in the blood picture after

enucleation or evisceration been observed. But sufficient observations have been made to justify careful neurologic study of all sympathetic ophthalmia cases, and the addition to local therapy, in perforating injuries, of treatment directed to the meningitic process namely, repeated lumbar puncture, intravenous urotropine, and glucose and salt solutions. Evisceration should only be done in cases of panophthalmitis. Operations for traumatic cataract should not be done too early. Patients with perforating eye injuries should not be discharged as cured until there is normal spinal fluid and normal hematology. M. Davidson.

Krückmann, J. *Choroiditis guttata* (Tay) and *honeycomb choroiditis* (Doyne). *Klin. M. f. Augenh.*, 1941 v. 107, Oct., pp. 361-372.

There is a certain similarity in the ophthalmoscopic pictures of these two entities. In both there are small yellowish-gray, almost punctate, opacities in the area about the macula. In choroiditis guttata the lesions are round, sharply defined, and more definitely yellowish, sometimes with a delicate pigment border. In honeycomb choroiditis they are polygonal (so as to suggest a honeycomb when they are closely packed), are more gray, much larger, and less sharply defined at their margins. In both, the normal retinal vessels pass undisturbed over the deeply placed opacities. Equal involvement of both eyes is an essential characteristic. Choroiditis guttata begins late in life, occurs preponderantly in females, may be familial, and is associated with normal vision, dark adaptation, and visual fields. It is probably produced by a drusen-like excrescence of the lamina vitrea and has no choroidal lesions, hence Dimmer prefers to call it retinitis

guttata. In Doyné's honeycomb chorioiditis there is almost always considerable loss of vision, and in cases which were observed for a long time there was a paracentral scotoma connected with the blind spot, as well as disturbances of light and color sense. In the only case which has been available for microscopic study Treacher Collins found hyaline degeneration of the lamina vitrea and over these areas of degeneration there was destruction of the pigment epithelium and neuro-epithelium.

Since the etiology is unknown it has been impossible to correctly classify all reported cases in the literature, and there is much confusion. The author reports the five cases observed at the Munich Clinic. Two of them seem to belong to one group and three to the other. Those disturbances in an individual patient which do not seem to be part of the textbook picture of one or the other of these entities are readily explained on the basis of concurrent pathologic changes. (3 figures, references.)

Roberts, W. L., and Nielsen, R. F. Uveoparotid fever with bilateral papilledema. *Amer. Jour. Ophth.*, 1945, v. 28, Nov., pp. 1252-1255. (References.)

Vila-Coro, Antonio. Notes on the treatment of tuberculous iritis. *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 172-179.

It is important to be conservative in the diagnosis of tuberculous iritis. Though the typical textbook picture of iritis is rare, patients in whom it occurs respond satisfactorily to specific therapy. On the other hand, when iritis is erroneously diagnosed as tuberculous on insufficient evidence the therapeutic results are disappointing and the value

of perfectly reliable therapeutic agents are misjudged. Once the diagnosis is reliably made tuberculin and calcium therapy are indicated. If they are ineffectual, sanocrysin in small doses should be used cautiously. The diet should be carefully supervised to guard against excess weight. In all resistant cases roentgenotherapy is indicated.

GLAUCOMA AND OCULAR TENSION

Barkan, Otto. Goniotomy. Preliminary deepening of the anterior chamber with air or saline solution. *Amer. Jour. Ophth.*, 1945, v. 28, Oct., pp. 1133-1134. (References.)

Carreras Durán, Buenaventura. Modern orientation in the treatment of glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 631-714.

This is an exhaustive treatise on the care of glaucoma. The pathologic background, mode of action, and indications for employment of the various forms of medical and surgical treatment are thoroughly discussed.

J. Wesley McKinney.

Casanovas, J. Roentgen irradiation of the cervical sympathetic in treatment of glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 594-607.

Ten cases of glaucoma were treated by irradiation of the superior cervical sympathetic ganglion. In some of them the tension was completely normalized, while in most of them the tension was lowered and the visual acuity and field improved. Pain was relieved in several cases. The procedure has some value

as an additional antiglaucomatous measure. (10 figures.)

J. Wesley McKinney.

Dashevsky, A. I. Tonometric "expression" testing and its clinical significance in glaucoma and traumatic ocular hypotony. *Viestnik Oft.*, 1944, v. 23, pt. 3, p. 21.

Since 1939 the author has been using the elastotonometer (devised by him and described in the 1941 *Viestnik*) to secure an expression curve found useful in early diagnosis, differential diagnosis, and control of the therapy of glaucoma. The curve is the graphic record of the rate of fall of ophthalmotonus during continuous application of the elastotonometer for two minutes, noting the fall every ten seconds. It is said to help in measuring the effectiveness of filtration after operation, in deciding whether miotics alone are sufficient to control the disease, and in measuring tension in the hypotonic state. It has been noted that hypotonic eyes with good light projection show an expression curve intermediate between the normal and the glaucomatous curve. In such cases treatment with dionin, hot paraffin compresses, and subconjunctival atropine injection gave encouraging results. (Illustrated.)

M. Davidson.

Díaz Domínguez, Diego. Causes of failure of antiglaucomatous operations. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 575-584.

Four principal causes of failure were noted in a series of 26 operations for acute glaucoma and 109 operations for chronic glaucoma. In the first group the cause of failure was use of iridectomy for a supposedly acute glaucoma which was in reality an acute superimposed upon a chronic glaucoma. Failure in

the second group was caused by waiting too long to operate in an acute attack not relieved by medical treatment. Failure in the third group was caused by injury to the lens capsule during operation for iridectomy. This complication is avoided by using the ab-externo incision. The fourth cause of failure was malignant glaucoma in which nothing seems to be of avail. (References.) J. Wesley McKinney.

Díaz Domínguez, Diego. The effect of internal administration of neurovegetative drugs on ocular tension in glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 771.

The double objective of the author's investigation was on the one hand to ascertain the vegetative disturbance of the glaucoma patient, and on the other to enlarge the list of drugs in glaucoma therapy. The material consisted only of cases resistant to local action of pilocarpine. Of drugs recommended as hypotensors in glaucoma, acetylcholine and pacyl were found totally ineffective. Hypodermic use of 0.5 mg. of eserine twice daily reduced intraocular tension in some cases and was ineffective in others. Atropine internally reduced the tension in 11 out of 17 cases, in five bringing it down to normal; the effect, however, was not lasting. In one eye in which pilocarpine locally raised the tension and intensified pain, the internal administration of atropine reduced the tension and enabled the eye to tolerate the pilocarpine. Ergotamine tartrate was found effective taken internally or injected subconjunctivally, except in eyes with advanced vascular deterioration; 1 mg. three times daily was frequently effective in cases in which the rise in intraocular tension was most marked in the afternoon. A more pronounced and lasting effect was ob-

tained with ergot alkaloids, which were found effective in cases in which gynergen failed. A combination of ergotamine, atropine and luminal was tried in 21 cases; it was ineffective in nine, effective in six, and unconvincing in six. It was ineffective in advanced cases or in cases with arteriosclerotic disturbances. Good results were obtained in cases which had been operated upon without complication but with inadequate reduction in tension. A combination of ergot alkaloids with a cholin derivative was tried in 27 cases, with transitory improvement in 3, a good result in 17, and no effect in 7. This combination of drugs was effective in cases in which each drug used alone had no effect on intraocular tension. The usual dosage was 0.5 mg. of ergot and 8 mg. of pacyl three times daily. The author is convinced that this combination is more effective than any other medication used in glaucoma, and urges its use in all cases of simple primary glaucoma in which miotics do not hold the intraocular tension within normal limits. The seven cases in which the treatment was ineffective were two of absolute glaucoma, three of acute glaucoma, one of infantile glaucoma, and one of secondary iritic glaucoma.

Ray K. Daily.

Díaz Domínguez, Diego. Ocular hypotension and primary glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 566-574.

The author notes that in primary glaucoma hypotension may occur spontaneously or after instillation of pilocarpine. It has also been noted in cases of glaucoma in one eye in which the other, normal eye may respond with hypotension upon instillation of pilocarpine. Such a reaction may indicate a predisposition to glaucoma, as the

tension of nonglaucomatous eye is usually not reduced by pilocarpine. The possibility of this hypotensive reaction should be kept in mind in cases of suspected glaucoma. (References.)

J. Wesley McKinney.

Krasilschikova, E. M. Carbocholin in glaucoma. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 45.

This preparation (carbaminol-chloride) used in twenty cases proved the most active of miotics. Its use makes pilocarpine more effective. When used immediately after tonometry general vagotonic effects were noted in the form of sweating, dizziness, salivation, nausea, and colic. This is attributed to sensitization by tonometry, and use of the drug is recommended not earlier than half an hour after tonometry.

M. Davidson.

Moreu, Angel. Fundamental basis of glaucoma therapy. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 745.

The author believes that the basis of glaucoma is an endocrine organo-vegetative disturbance affecting the oculo-vascular circulation. The oculo-vascular equilibrium of the eye is maintained by coördination of the ocular sympathetic and parasympathetic regulators, which are themselves subject to the influence of the endocrine glands. For etiologic therapy it is important to determine whether it is the function of the sympathetic or of the parasympathetic that is at fault. In the former the dominating process is vascular spasm with arterial hypertension, and the rise in intraocular pressure is caused by the secondary vasodilatation which follows every adrenergic vasoconstriction. In irritation of the parasympathetic there is primary vaso-

dilatation, and the slightest obstruction to venous drainage may upset the intraocular balance.

Another factor of therapeutic importance is the degree of adequacy of the intraocular venous and aqueous drainage. This is ascertained by gonioscopy and a fluorescein test used in the following manner: Five c.c. of fluorescein sodium is injected intramuscularly, and the patient placed immediately at the slitlamp. He is examined every half hour for the appearance of fluorescein in and its disappearance from the aqueous. The earlier it appears in the anterior chamber, the greater the vascular permeability and the more profound the vascular changes. The more rapidly it disappears, the more adequate the intraocular aqueous drainage. The higher the tension, the greater the drainage at the iridocorneal angle, a fact proved gonioscopically by the spot of fluorescein in the angle and by the green color in Schlemm's canal. In glaucoma with low tension and good drainage fluorescein is rarely found in the angle. This test has also a prognostic value; the later the fluorescein appears, and the faster it is eliminated, the better the prognosis.

Under treatment, in addition to local, hygienic, and dietetic regime, the author lays great stress on the importance of general medication acting on the neurovegetative system. The parasympathomimetics or cholinergics act by producing a primary vasodilatation without vasomotor paralysis; experimentally their oral, subcutaneous, or venous administration had no effect on intraocular tension even if the vascular pressure fell so low that the animals died. The author condemns the use of calcium in glaucoma. Cases with

obstruction to intraocular drainage, aqueous or vascular, belong to the domain of surgery. Ray K. Daily.

Moreu, Angel. Modern orientations in the pathogenesis and treatment of glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 548-565.

The author sets forth a working hypothesis which, he states, helps to elucidate the pathogenesis of glaucoma. Upon this hypothesis a system of treatment is based. It has been noted that in the preglaucomatous state the light threshold is lowered and dark adaptation retarded. These functions are tied up with the vitamin-A content of the retina and the melanotropic hormone produced by the hypophysis, which is regulated by the optic nerve itself and the cervical sympathetic. It is supposed that a sympathicotonus invariably exists in glaucoma, and that as a consequence the vascular bed of the uvea and retina is reduced and gives origin to a vitamin-A deficit in the retina. Vasoconstriction in the hypophysis produces diminution of production of the melanotropic hormone. This explains the alterations of the light threshold and dark adaptation in preglaucoma. After a time there is a paralytic vasodilatation especially affecting the ciliary body, with edema of the ciliary body and excessive transudation of blood plasma which cannot be carried away rapidly enough by the drainage channels. At this point hypertension ensues. Basing treatment upon the above outline concept of the pathogenesis of glaucoma, the author administers continuously the sympathetic depressant, gynergen, sometimes with the parasympathetic stimulant acetylcholine. Nicotinic acid is given for its

vasodilator effect. Treatment during the stage of hypertension is not discussed. (10 graphs.)

Palomar Palomar, Alejandro. *Cyclodiathermy punctures of Vogt in the treatment of glaucoma.* Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, July-Aug., pp. 608-617.

Discussing the mode of action and technique of Vogt's diathermy puncture the author gives the following indications for the operation: (1) hemorrhagic glaucoma, (2) acute glaucoma after medical treatment and iridectomy have failed, (3) glaucoma secondary to iridocyclitis in which iridectomy has failed, (4) painful absolute glaucoma, (5) glaucoma in aphakia and subluxation of the lens, (6) glaucoma with adherent leucoma after failure of iridectomy, (7) glaucoma in which the anterior chamber has disappeared, (8) glaucoma with markedly constricted fields in which other anti-glaucomatous operations may endanger the remaining field, (9) every case of glaucoma which other operations have not arrested the functional deterioration. (2 tables.)

Palomar Palomar, Alejandro. *Results of Vogt's cyclodiathermy in the treatment of hydrophthalmos.* Arch. de la Soc. Hisp.-Amer., 1944, v. 4, Sept.-Oct., p. 788.

The author reports four cases, one bilateral. In four eyes this procedure was the first operation, while in one eye it followed an unsuccessful Elliot trephining. In three eyes tension was reduced to normal and in two eyes the operation failed. The author believes that in infants this procedure reduces

intraocular tension as well as in adults. If successful the result is lasting, and the evolution of the glaucomatous process is arrested. Since most cases of infantile glaucoma are first seen in already advanced stages, when sclerectomy is dangerous, cyclodiathermy is here indicated as the first operative procedure; and in most cases it will save whatever vision is present. If there is any question as to its indication as the primary procedure, the author believes there can be no argument as to its indication in cases where sclerectomy or cyclodialysis has failed. In hydrophthalmos he considers this the operation of choice. Ray K. Daily.

Pérez-Buñil. *Extraction of the vitreous humor in the treatment of acute glaucoma.* Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, July-Aug., pp. 618-620.

In a case of glaucoma following corneal ulcer and iris incarceration, and in another case of acute glaucoma, about 0.7 c.c. of vitreous was removed through a large needle. In both cases the tension was temporarily normalized. In the first case iridectomy and in the second trephining was later done with good results

J. Wesley McKinney.

Romero, Eduardo. *Hypertension of the sympathicoradial system.* Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, Sept.-Oct., p. 797.

In the author's conception of the pathogenesis of glaucoma, the rise in intraocular tension in simple glaucoma is attributed to a spasm of the radial fibers of the ciliary muscle, innervated by the sympathetic. The theory is that the circular and radial fibers of the ciliary body are antagonists; the cir-

cular fibers functioning in accommodation for near and the radial in accommodation for distance, spasm of the radial fibers producing a fixed spasm of accommodation for distance, with a dilated pupil! The radial fibers we are told, are inserted into the tendinous ring of Dollinger, which forms the posterior wall of Schlemm's canal; their contraction creates mechanical obstruction to intraocular drainage and a consequent rise in intraocular tension. The effectiveness of surgical procedures such as iridectomy and cyclo-diathermy is attributed to destruction of the insertion of these fibers. Cyclo-diathermy destroys the fibers directly. The mydriasis of glaucoma is regarded as an expression of sympatheticotony affecting the radial ciliary and iris fibers.

Ray K. Daily.

Rossi, Silvano, Roentgen irradiation of the cervical sympathetic in glaucoma, *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 585-593.

This is a preliminary report based on the treatment of 18 cases of glaucoma by irradiation of the superior cervical ganglion. The results were encouraging. In the first few hours after irradiation there was usually a slight mydriasis with an increase in tension which lasted for a few hours. This phase was followed by miosis and lowering of tension. It is established that the autonomic nervous system has much to do with regulation of the ocular capillaries, ciliary body, and pupil, and thus the intraocular pressure. Glaucoma is thought to be due, at least in part, to imbalance of the autonomic nervous system. The action of X ray is selective, reducing the hyperfunctioning elements to normal. It is suggested that a single group of cells

may become hyperexcited, and that X ray in suitable doses acts only on this group of cells and not on the normal cells. (One graph.)

Vishnievsky, N. A. The diagnostic role of elastotonometry. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 15.

Elastotonometry, first proposed by Filatov, is believed to be a valuable aid in the diagnosis of incipient glaucoma but cannot be depended on exclusively for such diagnosis. Its basis is believed to be a change in plasticity of the ocular tissues. Experiments on rabbits, in which the fifth or upper cervical sympathetic was sectioned on one side, showed no appreciable effect on the curve. Nor was any effect noted on tonograms from repetition of the same weight or from changing the order of procedure from high to low heights or vice versa. Clinical application of the method in 117 glaucoma cases, with an incidence of hypertension in 39.8 per cent resulted in typical elastotonometric curves in 76 per cent of the cases. (Elastotonometry studies the rate of reduction of intraocular tension from application of increasing weights at regular intervals over a certain period.)

Wagner, H. Kerbacher, P., and others. Survey of operative results in over two hundred cases of chronic glaucoma treated with cyclodiathermy puncture at the University Eye Clinic, Zurich. *Klin. M. f. Augenh.*, 1941, v. 107, Nov., pp. 457-480.

Statistical compilation of the cases of chronic glaucoma treated with Vogt's cyclodiathermy puncture during the years 1936 to 1941, at the University Eye Clinic of Zurich, Switzerland, including Vogt's private patients. Most

of the cases had been operated upon previously by various methods and many were absolutely hopeless (lack of anterior chamber, hemorrhagic glaucoma, glaucoma from venous thrombosis, persistent high tension in spite of all surgical and medicinal treatment). In one of Vogt's private cases a hypopyon keratitis occurred two weeks after the operation. Otherwise not a single infection was observed. In many instances one cyclodiathermy puncture gave the desired result; in others more such operations, up to a maximum of nine, became necessary.

The following precautions are essential: perfect asepsis; strict care as to the length of the diathermy needles (not more than 0.5 mm.); keeping at least 3 mm. from limbus, to avoid lens injury and corneal lesions.

Cyclodiathermy puncture affords a patient with malignant glaucoma, uninfluenced by any other means, a fair chance not only to avoid enucleation but to preserve the function of the glaucomatous eye over a long period. The method is also suitable for painful absolute glaucoma. (2 tables.)

9

CRYSTALLINE LENS

Bischler, Vera. **Congenital total diffuse cataract.** *Klin. M. f. Augenh.*, 1941, v. 107, Dec., pp. 571-574.

The author reports on a cataract which was presumably inherited dominantly through four generations. Only one child was examined: a parent and the grandparents were aphakic and a great-grandfather was said to have had cataract. The child in question had a diffuse opacity of practically the entire lens. Only the central pellucid interval and the very narrow band between

the capsule and the subcapsular plane of cleavage were relatively clear. This is a more severe defect of the eye than the diffuse nuclear cataract described by Vogt, in that the patients had nystagmus, amblyopia, and a barely visible disturbance of the macula (the latter seen in the mother of the patient). On the other hand no retinal detachment complicated the operation. Vogt thought that his patients were predeposited to that complication. (3 figures, references.)

F. Herbert Haessler.

Cartwright, G. E., Wintrobe, M. M., and others. **Anemia, hypoproteinemia, and cataracts in swine fed casein hydrolysate or zein. Comparison with pyridoxine-deficiency anemia.** *Jour. Clin. Investigation*, 1945, v. 24, May, p. 268.

Swine maintained on a synthetic diet in which protein was supplied in the form of an acid hydrolysate of casein, or by feeding zein, failed to grow and developed an anemia. Lens opacities formed in two out of three pigs maintained on acid hydrolysed casein and in two out of three animals fed zein. The cataracts involved the posterior cortex and the suture lines. It is thought that the changes are caused by tryptophane deficiency. Although faulty tryptophane metabolism occurs in pyridoxine deficiency comparison between tryptophane and pyridoxine anemia reveals marked differences. A hypothesis is offered to explain the role of tryptophane and pyridoxine in hematopoiesis. The data presented suggest that a low intake of tryptophane retards the course and diminishes the severity of the nutritional disorder due to pyridoxine deficiency in swine.

Robert N. Shaffer.

Meyer, Gerhard. **Marfan's syndrome and spontaneous dislocation of the lens.** *Klin. M. f. Augenh.*, 1941, v. 107, Dec., pp. 580-584.

In four of five patients a spontaneous luxation of the lens into the vitreous produced a satisfactory visual acuity relatively early in life. With progressive displacement of the lens it is wise to postpone the highly dangerous extraction. The fifth case confirms this warning. The right eye became blind after operation. Dislocation of the lens into the anterior chamber is extremely rare in Marfan's syndrome. Pilocarpine is indicated in cases where this possibility suggests itself. (7 figures.)

F. Herbert Haessler.

Roethth, A. F. M. de, and Greene, P. B. **Rubella cataract.** *Northwest Med.*, 1945, v. 44, July, p. 222.

The historical background and the syndrome of rubella cataract are discussed. These congenital cataracts are due to infection of the mother by rubella particularly in the early months of pregnancy. Frequently associated are heart lesions, mental deficiency, and microcephaly. Therapy is surgical and linear extraction is preferred to discission, because of the toughness of the capsule. Two cases are reported.

Robert N. Shaffer.

Rosen, Emanuel. **An atypical case of Marfan's syndrome.** *Amer. Jour. Ophth.*, 1945, v. 28, Oct., pp. 1134-1138. (7 figures.)

Schönfeld, W. **Lichen disseminatus Vidal (neurodermatitis disseminata) and lenticular opacities.** *Klin. M. f. Augenh.*, 1941, v. 107, Dec., pp. 589-597.

Fifty-two cases of Lichen disseminatus Vidal have been reported and

this author adds five more. In two of his patients the associated cataract may have been a coincidental manifestation, and it is right to assume that this may also be true of some of the cases recorded in the literature. In three of his patients, however, the cataract was diagnosed by a colleague as cataracta dermatogenes. How the lesions of skin and eye are related has not been demonstrated. All of the author's patients who had cataract had also rather severe involvement of the skin, particularly on the face, and two patients had other allergic phenomena as well. The dermatologists are rather inclined to consider the skin lesion allergic in origin. It is possible that the ciliary epithelium becomes so altered that it allows anaphylactic antibodies to enter the aqueous from the blood and thus influences the metabolism of the lens. RETINA AND VITREOUS

Arruga, H. **A diathermy apparatus for retinal detachment.** *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 741.

Arruga has designed a simple diathermy apparatus with an output of 60 to 120 ma., adequate for diathermy coagulation in retinal detachment. The apparatus consists of a transformer of 125-2000 volts, a tungsten spark plug, three fixed condensers, a coil, and a rheostat. The accessories comprise a pedal for foot control, a neutral pad-electrode, cords, and a handle for the active electrodes. These last are straight and curved, olive tipped for coagulation, and sharp for perforation, and are insulated with glass.

Ray K. Daily.

Bartels Martin, **Accidental injury and retinal detachment.** *Klin. M. f. Augenh.*, 1941, v. 106, June, pp. 684-695.

We know nothing definite about the genesis of spontaneous retinal detachment. We know statistically that certain conditions favor its occurrence, and it is obvious that there must be varied opinions on the part that accidents play in its production. All we really know is that old and myopic eyes are more apt than others to have retinal detachment. It is not known whether a severe or slight or moderate myopia is most predisposed. Nor is it known whether degenerative changes associated with myopia make an eye more disposed and if so which changes, those of retina or of choroid. It is assumed that cystoid changes in the retina are particularly predisposed, but the author points out that cystoid degeneration is found also in normal eyes and even in youth. Nor is cystoid change in one particular area or stratum of the retina known to be particularly associated with retinal detachment.

To shed light on this problem Bartels selected for analysis 101 cases of his 417 in which trauma was mentioned. He concludes that after blunt injury there is almost always an interval between the trauma and development of the detachment. In cases ascribed to injury caused by heavy lifting or stooping he can see no connection but the detachment is almost always reported to have occurred immediately after the injury. This is also true of blows on the head. His conclusion from this experience is that when disturbance of vision is noted immediately after injury—aside from direct perforation or severe compression of the globe—the

injury has nothing to do with the detachment.

F. Herbert Haessler.

Franceschetti, A., and Babel, J. **Hemeralopia congenita and retinitis pigmentosa in a sister and a brother.** *Klin. M. f. Augenh.*, 1941, v. 107, Nov., pp. 506-521.

After discussion of the literature the authors report the cases of one sister with very pronounced congenital hemeralopia but without characteristic fundus changes and one brother with hemeralopia and extensive typical pigment degeneration of the retina. They conclude that from the clinical as well as the genetic standpoint congenital hemeralopia belongs to the group of retinitis pigmentosa and related retinal diseases. They propose a new classification of these ailments. (5 figures, bibliography.)

F. Nelson.

Gonzales, M. B. **Intraocular tension and retinal circulation in pregnancy.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., 802.

The conclusions from this investigation are as follows: (1) The intraocular tension falls as pregnancy advances and returns to normal one month after delivery. (2) The pressure in the central retinal artery remains unaltered in normal pregnancy and measures 50 per cent of the pressure at the forearm. (3) In toxemia of pregnancy the diastolic pressure rises 70 to 85 per cent of the tension at the forearm. This rise in diastolic retinal pressure appears before fundus changes become evident. (4) There is no relation between intraocular tension and retinal pressure. (5) During normal pregnancy the retinal vessels are tortuous and turgescient; at the onset of toxemia

they appear narrow but slightly tortuous and the fundus is ischemic. (6) Ophthalmoscopic examination enables us to make an early diagnosis of toxemia of pregnancy. For this purpose it is absolutely necessary to determine the relation between retinal and forearm diastolic blood pressures, the rise in diastolic retinal pressure being the first indication of toxemia. Graff, Gerd. Periphlebitis and tuberculosis, chorioretinitis in the same eye. *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 348-354.

The coincidental appearance of tuberculous chorioretinitis and periphlebitis in the retina is not an uncommon occurrence, as the author shows by means of statistics from the Freiburg Clinic, but the opportunity to photograph the fundus of such an eye rarely presents itself. Graff contributes such a composite picture made up of seven carefully matched fundus photographs, so that a relatively large area of the fundus is presented. The frequent association of periphlebitis and other ocular diseases which are known to be tuberculous makes it seem unlikely that periphlebitis of the retina is a manifestation of endarteritis obliterans, but the author is even more convinced by the fact that he has not seen a single case of Burger's disease in any of the many patients with periphlebitis in the retina. (4 figures, references.)

F. Herbert Haessler.

Karbacher, Paul. Retinal detachment and indirect trauma. *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 240-245.

After discussing various opinions concerning recognition of indirect trauma, especially to the head, as at

least an inducing factor for subsequent development of retinal detachment, the author reports briefly three cases of young (18 to 25 years) and absolutely emmetropic patients who developed retinal detachment following more or less severe head injury. (1 table.)

F. Nelson.

Lampert, H. The problem of clot shrinkage and its significance in retinal detachment. *Klin. M. f. Augenh.*, 1941, v. 106, June, pp. 625-638.

The author reports some of his experiments with silicate gel, particularly as to variations in the coagulum with changes in hydrogen-ion concentration. Passing an electric current through a solution caused the gel to adhere to the anode and to disappear from the cathode. Extending these experiments to blood in excised veins, it was possible to recanalize a clot and thus cause it to adhere to the vessel wall, preventing embolism. The relation to retinal detachment is discussed in a short paragraph in which the author states that the vitreous can be considered as a gel. The experiments have not yet been carried out as to the vitreous but information so obtained might throw light on moot points in the problem of retinal detachment (2 tables, 5 figures, bibliography.)

F. Herbert Haessler.

Meyer, W. An atypical case of retinitis punctata albescens. *Klin. M. f. Augenh.*, 1941, v. 107, Nov., p. 526.

A 42-year-old male, whose case had been diagnosed as one of retinitis pigmentosa when he was 17 years old, presented in the fundus a picture of rather typical retinitis punctata albescens. However, all functions were normal, including visual acuity, visual field, color perception, and dark adapta-

tion. There were no eye disturbances in the family. The condition was probably multiple drusen formation which did not impair any of the normal functions of the eye. F. Nelson.

Polojinteva-Demina, S. P. Vitamin-A starvation in adolescents, and effectiveness of carotene from pine needles in its treatment. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 38.

The examination of 136 children, one group in a school attached to a home for children and the other in a regular school, showed 9.8 percent suffering from lowered dark adaptation, and a low level of adaptation in 30.8 percent more. Those in the home fared better than the other group. Marked improvement of dark adaptation was noted in 14 out of 15 children in 5 to 14 days under use of carotene from pine needles. This improvement slowly disappeared on withdrawal of carotene. Fatigue after study periods was noted to influence adaptation. The testing was done with the Kravkov-Vishnevski apparatus, which, because of its portability and the speed with which the test can be administered, was found an excellent means of mass examination for early detection of lowered adaptation. M. Davidson.

Rieger, Herwigh. On the question of heredity in spontaneous idiopathic retinal detachment. *Klin. M. f. Augenh.*, 1941, v. 106, June, pp. 638-684.

In this 45-page lecture the author thoroughly discusses the part that heredity may play in the genesis of retinal detachment and critically evaluates the extensive literature on the subject. Vogt's views on the relationship between heredity, presenile degenerative changes, myopia, and retinal detachment are stated fully, but

the author does not believe that Vogt's position is very secure. Bartel's analysis of 500 to 600 cases of detachment suggest that familial occurrence of detachment must be quite rare. The author reports two family trees constructed from his own observations and lists about forty published by others. A report by Cibis has particular significance in that young hyperopic twins had similar detachments.

Detachment of the vitreous, however important, cannot be the only factor. It has been frequently demonstrated in eyeballs with disease of the choroid and the outer retinal strata, without any suggestion of detachment.

The author discusses the question whether one must assume the existence of a specific or nonspecific hereditary basis for idiopathic retinal detachment associated with myopia. Though nothing is proved he thinks it at least likely that a hereditary factor exists for production of the detachment that accompanies myopia. The particular manifestations which bring about hereditary detachment need probably not to be sought in the vitreous but in the retina itself. Abnormality of the glial tissue might be the basis of a progressive degenerative change in the retina comparable to abiotrophies of the central nervous system, in particular tapetoretinal degeneration. Clinically the detachment associated with myopia is characterized by almost constant presence of vitreous detachment, by a much greater incidence of retinal tear, and by much less developed histological changes in the region of the hole. The hereditary factor seems for the most part dominant but occasionally recessive. (2 figures, bibliography.) F. Herbert Haessler.

Rieken, H. A method of objective

adaptometry. *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 306-316.

The author adds to the communication given in his previous article (*Amer. Jour. Ophth.*, 1945, v. 28, Dec., p. 1401.) and offers further critical study of the method.

Rosenblum, M. E. **Localizing diathermy coagulation.** *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 19.

While localization by means of the ophthalmoscope is quite adequate for fundus lesions, such as tears and foreign bodies, correction of ophthalmoscopic localization is often indicated, particularly when an incision has to be so made as to spare the larger retinal vessels. For this purpose a localizing diathermy coagulation with ball electrode achieves greater accuracy. It produces in the fundus a yellowish spot which serves to control the incision. It has been found useful in extraction of magnetic foreign bodies by the posterior route, in extraction of nonmagnetic foreign bodies, and in extraction of subretinal cysticercus. Ophthalmoscopy during operation is not easy, but it is facilitated by doing it as soon as possible after the beginning of the operation and by attention to the cornea to prevent its drying.

M. Davidson.

Vancea, P. **The retinal hemorrhages of the new-born.** *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 272-274. (See Section 16, Injuries.)

Vilenkina, A. J. **The eye findings in war nephritis.** *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 35.

Among 58 cases studied ten were found with transient insignificant changes, and ten others with more marked changes, consisting of peri-

papillary retinal edema and narrowing of arteries. In only one case was there a true angiospastic neuroretinopathy. The conclusions as to prognosis are that the presence of permanent retinal changes represents a primary hypertension and poor prognosis, rather than a primary chronic nephritis.

VISUAL TRACTS AND CENTERS

García Miranda, A. **The central scotoma as an early symptom in the diagnosis of intracranial affections.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 465-474.

The finding of a central scotoma with or without papilledema or temporal pallor of the disc is usually indicative of an optic neuritis. Not infrequently, however, this loss of central vision is the first sign of an intracranial neoplasm which may be amenable to treatment. Further, opticochiasmatic arachnoiditis, tabes, and vascular lesions of the circle of Willis may be causative. Illustrative cases are cited. (4 figures, references.)

J. Wesley McKinney.

Giridhar, P. D. **Psychotherapy in hysterical amblyopia.** *Indian Jour. Ophth.*, 1945, v. 6, July, pp. 32-33.

The author relates three cases of hysterical amblyopia and one of hysterical amblyopia with monocular ptosis, all treated with immediately satisfactory results by means of subconjunctival injection of 1-percent salt solution, whose application had followed assurance that "a new and special medicine" would bring back the vision immediately. W. H. Crisp.

Kopil-Levina, E. A., and Shershevs-kaya, O. I. **The diagnosis and therapy of functional ocular affections in war-time.** *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 31.

Only eight cases of ocular neurosis in the material of three hospitals were noted. Interesting observations made on them were as follows. In the first place, in contrast to some statements in the literature, there was not noted any indifference of the patients to their plight or its duration, but on the contrary serious concern and an adequate psychic reaction to their functional derangement, and a sincere and exuberant joyfulness on their recovery from it. In the second place, purely functional visual field contraction is rare, and those resting on an organic basis are the majority. In the functional disturbances of central vision, there was noted as a rule an analgesia of the lids and orbit having a definite form of "spectacles" in bilateral cases and of a "monocle" in unilateral cases, that is where one eye had been enucleated. Hypnopsychotherapy not only restored vision to normal but eliminated the analgesia, without special reference to it by suggestion. Ordinary psychotherapy, without resort to hypnosis, gave no results. These cases had been

considered from four to eight months as organic cases, and it is believed that an earlier diagnosis would have cured them much earlier. The difficulties in diagnosis resulted from accompanying injuries of the face with possible organic sensory disturbance. The evolution of most cases was slow, and the rapidity of onset of the functional disturbance after the trauma is not an absolutely necessary clue to diagnosis. Correct diagnosis is important in that the other neuroses such as functional deafness, are liquidated simultaneously with the ocular neurosis, and the results influence favorably recovery from simultaneous organic affections. In one case, the suggestions given during hypnosis were made through an interpreter, with equally good results. Usually two sessions of hypnotic suggestion, by a method here referred to as that of Kopil-Levina, but not further described, were sufficient to restore vision from defective light projection, in some cases to normal. In two of the eight cases, with visual-field contraction only, suggestion alone was effective. One case was diagnosed as simulation, and restoration was effected by an order to return to duty. In this case no lid analgesia was elicited, but the patient alleged inability to open his eyes for ophthalmoscopy, and the diagnosis was based on these findings. M. Davidson.

Meyer, F. W. **Symptomatology of optico chiasmatic arachnoiditis.** *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 274-280.

Meyer describes the case of a man of 23 years who at 21 years rapidly developed a very marked dystrophic genital adiposis, diabetes insipidus with normal blood sugar, high spinal pressure, retrobulbar neuritis with cen-

tral scotoma, and atypical Argyll-Robertson pupils (pupils not miotic). Syphilis was ruled out serologically and otherwise. (References.)

EYEBALL AND ORBIT

Bielikova, L. P. The choice of material for implantation after enucleations. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 41.

On the basis of observation in 30 fat implantations, 11 implantations of sclera by the method of Medvedev, and 11 implantations of cadaver costal cartilage as suggested by Sverdllov, the author arrives at the conclusion that fat is the best implant. While sclera produces a good mobile stump, in some cases the postoperative edema is a disadvantage. Costal cartilage results in poor mobility of the prothesis. Only two cases of necrosis were noted in the fat implants. The presence of an inflammatory process is not considered a contraindication to use of fat.

M. Davidson.

Bursuk, G. G. Use of gastrocnemius aponeurosis in plastic surgery of the conjunctiva. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 13.

In the restoration of contracted sockets, very satisfactory results are described from use of gastrocnemius aponeurosis. It is not subject to shrinking, is viable, and retains the form impressed on it. In 10 to 14 days it assumes the color of conjunctiva. The skin incision for obtaining the aponeurosis transplant has the shape of a half ellipse with convexity below and outside the crista tibiae. This incision prevents tearing out of the sutures. The aponeurosis is sutured to the un-

dermined conjunctiva. The prothesis can be put in immediately or on the following day and the sutures taken out in four or five days. Ten case histories are given, some with contracted sockets, others with complete or partial symblepharon. M. Davidson.

Filatov, V. P. An enucleation procedure. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 3.

In war surgery, where adequate and accurate anesthesia is not always possible and where enucleation is likely to be unusually painful because of the presence of orbital scars, a modification of Tillaux's procedure has been found of great advantage in dozens of cases. This method proceeds from behind forward instead of from before backward. After undermining the conjunctiva and sectioning the internal rectus, the optic nerve and ciliary nerves are cut first, and under widest possible retraction of the lids by the assistant, the globe is dislocated outward and with the aid of a sharp double hook the posterior pole is brought forward as in neurectomy. The obliques are next cut and then the remaining recti are sectioned. In cases with scars and adhesions of the globe to the inner orbital wall, Tillaux's original method of cutting the external rectus and dislocating the globe inward may be substituted.

M. Davidson.

Jaensch, P. A. Posterior orbital cephalocele. *Klin. M. f. Augenh.*, 1941, v. 107, Dec., pp. 561-571.

In the large subject of brain herniation only two manifestations interest the oculist, namely anterior (naso-orbital) and posterior (spheno-orbital) orbital cephalocele. The latter is rare

and the author therefore records two case histories. Diagnosis depends on the observation of pulsation of the eyeball without bruit and an exophthalmos with displacement of the eye down which is easily reduced by pressure and is followed after a time by transient enophthalmos. A roentgenogram is of great value. Only 24 cases have been recorded thus far. Mortality is high. Most of the patients are young, symptoms develop very gradually, and the average duration is 14 years. The first of the author's patients is remarkable in that the disease started in early childhood after injury and now at the age of 79 years the patient still enjoys a good reputation as an active and capable business man and hunter. The other patient, a 32-year-old woman, also presented the typical clinical picture. In her roentgenogram the absence of bone is so great that it is probable the right orbit is separated from the interior of the skull only by a membrane. On stereo-plates one has the impression of looking through the skull. In both patients the roentgenogram suggests bone destruction by a malignant neoplasm, but there is no known growth that continues to exist for 30 or even 79 years. (5 figures, bibliography.) F. Herbert Haessler.

Johnson, L. V. A simple rubber form for the reconstruction of a contracted socket. *Amer. Jour. Ophth.*, 1945, v. 28, Nov., p. 1260.

Kozmin, V. I. Electrocoagulation of of the conjunctival socket in plastic operations. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 40.

Free transplants have not provided the author with permanent results in dealing with contracted sockets. The best results have been from the use of

scrotum, which is thin and elastic. Superior results have been achieved by electrodiathermy coagulation. It has the advantage of economy of palpebral tissue, rapidity of scar formation, and minimal shrinking. The conjunctiva is deeply undermined both anteriorly and posteriorly, the underlying scars thoroughly burned out, and the conjunctiva replaced (sometimes sutured). The prosthesis is immediately put in and is kept for 7 to 10 days. The result is a deep and permanent fornix holding the prosthesis well.

Senna, Sertorio. A rare and grave complication of enucleation. *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 814.

Senna reports two cases of severe hemorrhage, one six days after the enucleation, and the second immediately after section of the optic nerve. Each was controlled by a deep purse-string catgut suture which compressed the deep orbital tissues, including the optic nerve.

Ray K. Daily.

Sudakievich, D. I. The first experience with use of plastic material for orbital prothetization. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 43.

The use of plastic material was begun in March, 1943. The addition of pigment—the most useful ones being pink and yellow—results in a prosthesis equal in semitransparency and delicacy of color to that of glycerine-gelatin. The prosthesis is attached to a spectacle frame. Because of complicating bone injuries in these cases, close cooperation between the surgeon and the prothetist is required in achieving good results. In some cases a rubber prosthesis serves best.

EYELIDS AND LACRIMAL APPARATUS

Awerbach, M. I. Some remarks anent Strakov's article on dacryocystitis in peace and war. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 9.

As partly responsible for the thesis of Ivanova referred to in Strakov's article (see below), the author points out that, in spite of apparent contraindications on theoretical grounds, successful rhinostomies have been performed. He suggests that the suturing is not so important as the size of the osseous window achieved, and that many operators use sutures sparingly. The author believes that he who knows how to do a dacryocystorhinostomy is capable of doing an extirpation, should the occasion present itself, but that he who has only learned to do an extirpation is handicapped in doing the other without special training.

M. Davidson.

Brown, J., and Cannon, B. Full-thickness skin grafts from the neck for function and color in eyelid and face repairs. *Annals of surg.*, 1945, v. 121, May, p. 639.

Full-thickness grafts from the neck and clavicular region have been found to give superior results in the repair of facial defects. Two main advantages are improved function and color. The color is nearly always close to that of the normal face. Good function is due to thickness and softness and possibly also the character of the skin which naturally overlies a platysmal muscle. Main areas for use are on the lids, in the canthal regions, about the ala, over the nose, and about the eyes and the angles of the mouth. The authors present diagrams and pictures,

and discuss procedures involving skin grafts in facial repair.

Theodore M. Shapira.

Davids, Hermann. Contribution concerning treatment of dacryocystitis phlegmonosa. *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 238-240.

Treatment is, if possible, conservative. If repeated cautious massage and poulticing fail to produce pus either upward or downward the lower canaliculus is probed, but the probe is only introduced into the sac, not into the lacrimonasal duct. While the probe is being slowly withdrawn, the author again attempts to evacuate pus by gentle massage. If that attempt is unsuccessful he tries to aspirate pus through a blunted irrigation needle. This is usually easy to do. Pus is to be expressed first every two hours, later four to five times daily, then three times daily. Apparently this routine by no means makes later operation on the tear sac unnecessary.

Saurez Villafrance, M. R. New contributions to palpebral surgery. *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 816.

The distinctive features of the author's technique are: (1) Preoperative preparation of the forearm from which the grafts are cut; the arm is dressed

with an antiseptic dressing for four days preceding the operation. (2) Forceps which the author devised for holding the graft; they are similar to hemostats except that they end in sharp cross-action prongs; the one-pronged model is used for small grafts, while the two- and three-pronged instruments hold larger grafts. The claim made for them is that they minimize the trauma to which the grafts are subjected in holding, and thus reduce the danger of necrosis. (3) For cicatricial ectropion of the lower lid the author uses Elschmig's free transplants. (4) For restoration of the lower lid and conjunctival sac he resorts to a combination of a deep free graft, a superficial sliding graft, and the lower third of the tarsus of the upper lid. (5) Repair of traumatic coloboma of the lids is done with the sliding flaps of Celsus and Knapp and excision of Burrow's triangles, supplemented by a third fatty-cutaneous flap from the cheek. (Illustrations.) Ray K. Daily.

Soria. Twenty years of dacryocystorhinostomy. *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 807.

Soria reviews briefly the evolution of his technique since he began the Toti operation twenty years ago. Anesthesia is achieved through the three subcutaneous injections described by Chevrier and Cantonnet for extirpation of the lacrimal sac supplemented by topical intranasal cocaineization of the operative field. The osseous orbitonasal perforation does not exceed 9 mm. in diameter, and is placed as low as possible to avoid making the lower portion of the sac a reservoir for secretion. The bone is carefully perforated with an electric trephine, supplemented by the use of a chisel if

necessary to avoid injuring the nasal mucous membrane. The posterior lip of the incised lacrimal sac is sutured to the incised nasal mucosa; the anterior lip of the sac is sutured to the periosteum at the bony opening into the nose. Suture of the skin and a compressive bandage complete the procedure. To facilitate trephining and avoid friction between trephine and bone, the writer devised a trephine tip with sawlike teeth which are inclined alternately slightly in and out. The periosteal elevator is a reduced model of the large elevators used in general surgery. A protector longer and wider than those commonly in use guards the lacrimal sac from injury during the trephining. Stress is laid on the importance of postoperative irrigation of the new drainage channel; this is begun as soon as the cutaneous sutures are removed. The irrigation cleanses the deep wound of secretions, washing them into the nose; it also stimulates epithelization of the denuded areas, and prevents development of granulomata, which might cause a poor surgical result. (Illustration.)

Spaeth, E. B. Acquired blepharoptosis. *Amer. Jour. Ophth.*, 1945, v. 28, Oct., pp. 1073-1087. (1 table, 49 figures, references.)

Strakov, V. P. Dacryocystitis in peace and war. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 4.

The author reviews the progress in treatment of dacryocystitis from the time, fifty years ago, when the most conspicuous group of patients in the Moscow Eye Clinic were those with lacrimal sounds in their tear passages and dark bands of argyrosis on their

faces, from the silver-nitrate irrigations to which they had been subjected down to the dacryocystorhinostomies of our days. The author believes that many cases of epiphora can be handled conservatively, and he is against the advocacy by some authorities, particularly Ivanova, of abandoning extirpation entirely in favor of dacryocystorhinostomy. The latter he believes contraindicated (1) when the canaliculi are impermeable or non-functioning, since their role in tear conduction is paramount; (2) when there is likely to be difficulty in suturing the sac to the nasal mucosa, because of atrophy or fragility of the sac wall or hydrops of the sac with diverticuli; (3) in the presence of paranasitis, especially ethmoiditis; (4) in tuberculosis of the sac or acute dacryocystitis; and (5) in the aged and feeble. Prevention of epiphora from war injuries is important, and careful suturing of canaliculus injuries is the chief means of achieving it. In 1942 and 1943, in one evacuation hospital there were performed 101 dacryocystitis operations—70 percent dacryocystorhinostomies and 30 percent extirpations. In the 12 traumatic cases extirpation and rhinostomy were equally represented. Because of scar tissue and bony deformations in these cases canaliculorhinostomies had to be performed. In the absence of studies of end results of rhinostomy in the U.S.S.R. the author believes that the young ophthalmologist should be trained in sac extirpation and that a well-done extirpation is better than a poorly done dacryocystorhinostomy. TUMORS

Goodsitt, Edward. Metastatic carcinoma to the choroid arising from the

lip. Amer. Jour. Ophth., 1945, v. 28, Nov., pp. 1256-1259. (5 figures, references.)

Kreibig, Wilhelm. The clinical diagnosis of angioma of the choroid. Klin. M. f. Augenh., 1941, v. 107, Dec., pp. 597-621. (9 illustrations, including 1 color plate, references.)

Of the fifty choroidal angiomas which have been reported since 1885 all but 15 were discovered in histologic studies of blind eyes. Of the 15 eyes which had been studied ophthalmoscopically the majority were enucleated with a clinical diagnosis of sarcoma.

The diagnostic characteristics must be evaluated with caution since most of the manifestations could also occur with sarcoma. Sooner or later an angiomatous eye leads to blindness and must be removed for painful glaucoma, hence enucleation is indicated when in doubt because the alternative diagnosis is sarcoma. The most helpful manifestation is extensive angioma of the skin of the face surrounding the eye. The color is also suggestive. It is described as pale yellowish-red with striking bluish and greenish reflexes from the steeper edges of the protruding mass. The tumor itself is always much more extensive than the protruding mass. Slight or absent pigmentation on its surface suggests angioma. An irregular knobbed surface suggests angioma. Juxtapapillary site not involving the disc also speaks for angioma. Macular degeneration with areas of cicatricial membrane is not uncommon, and occurrence during youth is suggestive.

The reported cases may be naturally divided into two classes: (1) those that are associated with facial angioma, that have had amblyopia since childhood, and that are certainly congeni-

tal; (2) those that have evidence of having had perfect vision, that have no facial hemangioma, and in which the manifestations of tumor arise later in life. The author reports in great detail clinical and histologic studies of three cases. F. Herbert Haessler.

Velhagen, K. Diagnostic puncture when suspecting choroidal sarcoma. *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 354-361.

Velhagen describes his findings in three cases of choroidal sarcoma where diagnostic puncture was permissible and indicated. The procedure is not without danger, because any trauma to an eye afflicted with a malignant growth increases the danger of immediate metastasis although puncture is perhaps not so dangerous as is generally believed. The procedure is particularly valuable when vitreous hemorrhage obscures the view or when a large retinal detachment accompanies a small sarcoma. As one of the author's cases shows, a retinal tear may occur even in detachment caused by choroidal sarcoma. In the first enucleation for sarcoma which he saw as Axenfeld's assistant, the condition turned out to be a simple serous detachment. If diagnostic puncture is to be done, it is important to strive to obtain a specimen of subretinal fluid with as small an admixture of blood as possible. Three examinations should be made: (1) of smears from the material obtained by centrifuging the specimen of subretinal fluid; (2) a paraffin section of the same; (3) the melanin reaction described by Cibis.

Microscopic study of the preparations referred to in (2) reveals blood corpuscles, fibrin networks, and large irregular cells, occasionally with pig-

ment and large irregular nuclei. These cells are not round or spindle-shaped as one expects from histologic preparations of the tumor. They occur singly and in clumps of various sizes. It is important to draw diagnostic conclusions only from a study of clumps of cells. The single cells may not be reliably distinguished from ciliary-body epithelium or large histocytes such as are also seen in serous detachment.

For the Cibis melanin reaction one places a drop of subretinal fluid on a piece of filter paper which has been saturated with ferric chloride. When the reaction is positive for melanin the area becomes brown and remains so. The albumin of the exudate coagulates and the brown spot becomes sharply defined. In a negative reaction the area on which the fluid was dropped becomes paler.

Two pairs of illustrations show the appearance of cells from the subretinal fluid as compared with a histologic section of tumor from the same eye. (4 illustrations, references.)

INJURIES

Baltin, M. M. Treatment of facial burns with Bucky's border rays. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 27.

In second-degree burns, involving lids, the use of bucky rays has proved most effective in the prevention of scar formation due to secondary infection of vesicles. The rays are analgesic, and promote rapid epithelization and drying up of secretion. Any scabs, or caking of streptocide powder, prevent penetration of the rays. Hence the method is not effective in third-degree burns. M. Davidson.

Baltin, M. M. The extraction of intraocular foreign bodies. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 20.

Difficulty in extracting with the magnet is no proof of nonmagnetic nature, as is often hastily assumed. Greater accuracy in X-ray localization is being achieved by the Comberg-Baltin procedure. Making the scleral opening as close as possible to the foreign body is perhaps more important than prophylactic electrocoagulation. Other points are discussed.

M. Davidson.

Bartels, Martin. Accidental injury and retinal detachment. *Klin. M. f. Augenh.*, 1941, v. 106, June, pp. 684-695. (See Section 10, Retina and vitreous).

Brodsky, B. S. New permanent hand magnet in the light of present-day magnet-operation methods. *Amer. Jour. Ophth.*, 1945, v. 28, Nov., pp. 1245-1251. (2 figures, references.)

Brodsky, B. S. Scleral opening in the extraction of magnetic foreign bodies. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 38.

Sectioning the sclera with a knife, whether meridionally or tangentially, has disadvantages. The foreign body may catch in the lips of the incision, and the incision has often to be enlarged to permit extraction. The author has made use of the Filatov-Martinkovsky trephine of 1.5 to 2 mm. diameter (with either a sealed partition or a movable piston inside of it) to remove a scleral disc which is sometimes left on a hinge. The choroid and retina are not opened by incision, but are perforated by the foreign body in its exit. The disc is replaced and only conjunctiva is sutured over it. In only two cases was it necessary to incise the

choroid, and in only one case was introduction of the magnet tip into the vitreous necessary. M. Davidson.

Friedman, S. J. The prophylaxis, diagnosis, and treatment of sympathetic ophthalmia in the light of further observations. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 37. (See Section 7, Uveal tract, sympathetic disease, and aqueous humor.)

Friemann, Werner. Prognosis of simultaneous eye and brain injuries. *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 265-271.

Friemann reports the case of a railroad worker who suffered a perforating injury of the right eyeball and orbit. A splinter, probably a piece of iron, had entered the brain and could be localized in the right temporal lobe (X ray). The vision of the injured eye was lost at once, and the eye was eviscerated because of danger of sympathetic ophthalmia. In contrast to many other observations which lead to the assumption that the prognosis of such combined injuries is usually very doubtful or hopeless, this patient did not show any neurologic or psychiatric symptoms during an observation period of 3½ years, with the exception of a moderate forgetfulness and occasional conditions which might be construed as epileptiform mental absences. F. Nelson.

Goldfeder, A. E. Plastic operations to repair the wider palpebrofacial defects from gunshot injuries. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 27.

All defects may be classified into two major groups, of which there are several subdivisions. One group has essentially a triangular form, with apex on cheek and base corresponding

to palpebral fissure, and is the most common, 13 such cases being here mentioned. The less common group is more or less quadrangular, with a side instead of an apex on the cheek. Three such cases are cited. The principle followed was to utilize the mucosal floor of the defect to reconstruct scar tissue of the border of the defect for formation of the lower fornix, inner layer, and lid border; and a skin-cartilage flap from the ear for the outer layer. Sutures are used only when the transplant shows a tendency to shift its position with eye or jaw movements. The first group is repaired in one stage, the second in two stages, with two to three weeks interval. The first stage diminishes the area of the defect, while the second stage reconstructs the lower lid and border, out of the transplanted flap alone or in combination with mucosa. This operation is best done 4 to 5 months after injury. The contraindications are: osteomyelitic processes, dacryocystitis, excessive hyperemia of the defect, and friability of its floor. The same method has been applied to rebuilding the upper lid. The results have been highly satisfactory from the cosmetic as well as the functional viewpoint. (Illustrated.)

M. Davidson.

Hofe, K. vom. **Clinical contribution to the understanding of keratitis neuroparalytica.** Klin. M. f. Augenh., 1941, v. 107, Aug., pp. 154-159. (See Section 6, Cornea and sclera.)

Ivanova, N. K. **Magnet extraction of foreign bodies from the ciliary body.** Viestnik Oft., 1944, v. 23, pt. 6, p. 9.

In the special hospital for magnet extraction, 347 foreign bodies were extracted from eyes, and 67 attempts were unsuccessful. Extraction was di-

ascleral in 89 percent of the cases, including 8 percent from the ciliary body. Attempts in two cases to extract the foreign body from the ciliary body via the anterior route, while removing the cataractous lens were unsuccessful, but the aim was accomplished satisfactorily by the posterior route. The 30 foreign bodies in the ciliary body had entered via the cornea in 6, via the limbus in 7, and via the sclera in 17 cases. Four of them were in the opposite part of the ciliary body, and almost all in the lower part of it. The fragments varied in size from 1 by 1 mm. to 5 by 2.5 mm., the majority being less than 3 mm. Hemophthalmos was present in more than one half of the cases. Because of delays in intermediate stations, the extractions were done in one half of the cases between eight and thirty days, in the other half up to six months after injury. In a few cases the ciliary body had to be incised for removal. Magnet testing was found a sound procedure, since extraction was unsuccessful in the only two cases where the test was not positive. The eye had to be enucleated in only two cases. There were no complications otherwise. The end results however are not available, because of early transfer of the patients to rear hospitals. The author regards removal of foreign bodies from the ciliary body as no more dangerous than from other parts of the eye.

M. Davidson.

Kaminskaya, Z. A. **The surgical treatment of hemophthalmos.** Viestnik Oft., 1944, v. 23, pt. 6, p. 3.

While hemophthalmos is one of the most frequent complications of contusions and perforating injuries, neither the source of the hemorrhage nor the process of its absorption are yet quite clear, particularly with reference

to retrolental hemorrhages. According to Fuchs, hemolysis and absorption begin in three or four days, take six to eight weeks, and are accomplished by the nonpigmented cells of the ciliary epithelium. The coagula formed in the neighborhood of the source of the hemorrhage requires a longer period for disintegration and absorption. The metabolism of the vitreous is thereby accelerated, and it liquifies and becomes impregnated with fine pigment dust (visible with the slitlamp. and at times with the formation of synchysis scintillans particles. Absorption is retarded by proximity to the globe wall and lens, and by inflammatory reaction while blood from the central part of the vitreous is more readily absorbed. The main purpose of treatment - is to prevent formation of connective-tissue bands from glial proliferation, and their contraction incident to the presence of unabsorbed blood. The most effective method for stimulating absorption has been found to be Zur Nedden's aspiration of vitreous, and excellent results were achieved in 19 out of 25 cases in which this was applied. In some cases a preliminary scleral incision with a knife was used before introducing the needle. In these cases it was noted that the blood accumulation was not only in the vitreous but in the perichoroidal space, from which, before puncturing the choroid, large quantities of hemolysed blood would pour out. Aspiration was performed every six weeks, beginning with three drops and increasing to six drops. The visibility of the fundus and the visual acuity were noted to increase after the first aspiration.

Katznelson, A. B. Orbit and sinus injuries with foreign bodies in the sinuses. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 14.

Thirty-six cases of foreign bodies in the sinuses and outside of them are reviewed from clinical and localization aspects. Of the nine sphenoidal cases two presented the "traumatic superior orbital fissure syndrome" with exophthalmos, ptosis, ophthalmoplegia, and neuromyolytic keratitis. In the non-traumatic syndrome only corneal anesthesia results, from involvement of the trigeminal nerve. Two cases of optic atrophy were included. The fundus lesions were usually double: one at the point of contact and the other one at the posterior pole. Recurrent intraocular hemorrhage was observed in some and was attributed to injuries to the venae vorticosae. The rhinologic symptoms were not marked. The 11 ethmoidal cases showed the most inflammatory reaction. There were five frontal-sinus cases. Among the 11 antrum cases five foreign bodies were found in the contralateral antrum. The antrum cases were characterized by neuralgia of the infraorbital nerve, and by more serious globe injuries, eight of the 11 requiring enucleation. The cerebral-contusion symptoms in all of them were rather mild.

M. Davidson.

Klien, B. A. Chronic posttraumatic syndromes leading to enucleation. *Amer. Jour. Ophth.*, 1945, v. 28, Nov., pp. 1193-1203. (3 tables, 8 figures, references.)

Kopp, I. F. The surgical problem in perforating injuries of the ciliary-body

region. *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 18.

The pessimism of the past in regard to ciliary-body injuries is not valid today. It should be borne in mind that it is not the injury to the ciliary body itself but the method of handling it and its role in the supervening iridocyclitis which are important. Many apparently hopeless cases may be salvaged by proper handling of the wound. This requires careful inspection, complete analgesia, and adequate akinesia. Prolapsed vitreous should be ablated, and prolapsed ciliary body replaced if recent and excised if exposed for longer than 48 hours. A gaping scleral wound is sutured. The results of proper handlings have been as follows: Only one eye out of 11 was lost in industrial-injury cases with retained foreign bodies; while those saved were 7 cases out of 19 nonindustrial injuries without foreign bodies, late in securing treatment, and 10 already showing panophthalmitis; 22 out of 30 war injuries seen late (5 days or longer after injury); and 14 out of 18 cases seen early.

M. Davidson.

Kovalevsky, P. S. Results of secondary hermetic closure of granulating wounds of the lids and adjacent areas. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 45.

Primary suture of wounds of the lids and adjacent areas is effective only within six hours after injury. Even then, under war conditions, resulting infection undoes the work. The result is an ugly large granulating surface, which if neglected is difficult to handle afterward. Secondary suturing is however feasible within six days, or, in case of infection, within 12 days after injury. The results are smoother scars with less tendency to adhesions. At

times it is impossible to close the whole open wound, but much is accomplished by partial closure. It is helpful sometimes to freshen the borders of the defect before suturing. Granulating surfaces should be closely approximated, pockets avoided, and when it is impossible to avoid these drainage is provided for by tampon. In 187 cases this has not resulted in a febrile reaction, and the convalescence period has been hastened. M. Davidson.

Krasnov, M. L. An unusual foreign body in the orbit. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 10.

This unusual case is reported to illustrate the fallibility of X ray and anamnesis. A young soldier was injured while wrestling, in the course of which he struck his right eye and the root of his nose. The left eye became blind. The X ray was negative. Neurologic examination was negative except for ophthalmoplegia and amaurosis. The diagnosis was cerebral concussion with orbital hemorrhage. While in the hospital for observation, two weeks later, the patient developed an abscess above the inner canthus of the right eye. Incision and exploration revealed a 2½-inch piece of lead pencil which had penetrated the right orbit, passed through the ethmoids and injured the left optic nerve, with permanent optic atrophy resulting. A re-examination of several X rays previously reported as negative showed faintly the outline of the pencil with the lead traceable through it. After operation the ophthalmoplegia disappeared. M. Davidson.

Krückels, H. Burns of the eye with brilliant green. *Klin. M. f. Augenh.*, 1941, v. 106, May, p. 571.

Brilliant green is an aniline dye used

in treatment of various skin diseases, especially chronic eczema, fungus diseases, and parasitic skin lesions. Already in 1912 Römer's, Gebb's and Löhlein's experiments proved that application of a 1-percent watery solution caused chemosis in rabbits' eyes. A case is reported. The patient had been treated by an oculist for simple conjunctivitis for a considerable time. Eventually the doctor prescribed a 1-percent brilliant-green solution. There resulted severe destructive hypopyon keratitis with necrosis of the conjunctiva, terminating in bilateral blindness with good light projection.

McCulloch, Clement. **Changes at the macula due to solar radiation.** Amer. Jour. Ophth., 1945, v. 28, Oct., pp. 1115-1122. (2 diagrams, references.)

Mielke, Sophus. **Rusting of intralenticular iron splinters.** Klin. M. f. Augenh., 1941, v. 107, Oct., pp. 422-425.

Mielke describes an eye with an intralenticular ferruginous foreign body in which the significant observation was rusting of only the anterior tip of the splinter while siderosis spots were already present under the anterior capsule. It is probable that the distribution of metallic ions in the ocular tissues depends upon the action of a current and that accumulations take place behind relatively impenetrable membranes (lens capsule and Descemet's membrane in chalcosis). When an electrolyte lies in the path of an electric current it becomes a secondary conductor, that is, its end which is directly toward the anode becomes a cathode and the other end an anode. Observation of this case of intralenticular foreign body suggests

that the current flows toward the anterior part of the eye. Particles will be carried only from the anode (that is the anterior end) into the tissues, to be deposited behind the first effective barrier, the lens capsule, which is the characteristic site of siderosis spots. The author has done experimental work to elucidate these facts, but this is the first clinical observation that confirms his experiments. (1 figure, references.) F. Herbert Haessler.

Moncreiff, W. F., and Scheribel, K. J. **Penetrating injuries of the eye.** Amer. Jour. Ophth., 1945, v. 28, Nov., pp. 1212-1220. (11 tables.)

Paez Allende, Francisco. **Foreign bodies on the cornea.** La Semana Med., 1945, v. 52, Sept. 6, p. 371.

The author insists on the importance of using thorough preliminary lavage (after complete anesthetization) before employing a foreign-body needle, especially when the foreign body is in the pupillary area. W. H. Crisp.

Peter, A. L., and Rosen, E. **The importance of injecting air into Tenon's capsule even in cases of foreign bodies within the eyeball.** Amer. Jour. Ophth., 1945, v. 28, Oct., pp. 1140-1144. (4 figures, references.)

Plitas, P. S. **The extraction of non-magnetic intraocular foreign bodies.** Viestnik Oft., 1944, v. 23, pt. 4, p. 4.

The author gives a detailed statement of his own technique.

Protopopov, B. V. **Matched blood and plasma transfusion in iridocyclitis.** Viestnik Oft., 1944, v. 23, pt. 6, p. 12.

The author has used blood transfusion in traumatic iridocyclitis in 120 cases. Matched blood was used in one

hundred cases, after plasma use in twenty cases was found ineffective. In the cases with foreign-body retention, transfusion was used both before and after extraction. Local therapy when indicated was not neglected. The results in 35 cases were notably good, with relief of pain and tenderness, lessening of ciliary injection, photophobia and lacrimation, rapid absorption of exudates and hemorrhages, normalization of intraocular pressure, greater effectiveness of mydriatics, and better wound healing. Less significant improvement was shown in 44 cases. In 19 cases no improvement was noted, and two cases were worse after use. The author therefore considers transfusion useful and from experimental work on rabbits he concludes that the measure acts as desensitizer of the eye.

M. Davidson.

Radzikhovsky, B. L. **Sequestrotomy in gunshot orbital injuries.** *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 34.

In one base hospital 20 percent of all gunshot orbital injuries were complicated by osteomyelitis, and 31 cases were operated upon. The best time to operate has been found to be 1½ months after injury, when all inflammatory reactions have subsided and only a fistula remains. The help of the rhinologist is invoked when the sinuses are involved, and that of the neurosurgeon when intracranial extension is suspected.

M. Davidson.

Ratinova, K. A. **Some therapeutic procedures in traumatic iridocyclitis.** *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 14.

When other methods fail, two procedures have proved of benefit. (1) Decompressive scleral trephining: Based on observation of beneficial effect of attempts at removal of foreign bodies

in the presence of an inflammatory reaction, even when the attempt was unsuccessful, the author has used it in 16 apparently hopeless cases, 13 of them with nonmagnetic foreign bodies retained. A scleral flap instead of a linear incision is used. Only in four was the choroid opened. In some cases the procedure acts as would an anti-glaucomatous operation although its effect is attributed to reduction of inflammatory uveal tension. Hemophthalmos was present in three cases. Three eyes had to be enucleated. Of the rest, in two improvement ranged from light perception to hand movements. (2) Retrobulbar injection of 40 percent alcohol with 1 percent novocaine. This was used in 45 cases. It is a most potent analgesic, when for psychologic reasons enucleation is not feasible, as is the case in the young one-eyed person.

Satz, L. B. **A case of fatal purulent meningitis following an eye injury.** *Viestnik Oft.*, 1944, v. 23, pt. 6, p. 47.

In the case described an injury apparently limited to the eye, and resulting in its enucleation, led to meningitis because of an overlooked intracranial foreign body. M. Davidson.

Scharf, Josef. **Demonstration of an intraocular foreign body by means of gonioscopy.** *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 193-196.

A patient suffered a penetrating injury of the globe while cracking coal. It was impossible to demonstrate the presence of a foreign body with the help of the ophthalmoscope, slitlamp, or roentgen ray. The eye healed and became relatively quiet, but in four years severe inflammation reappeared. By this time gonioscopy had become available and a foreign body which had characteristics suggesting wood was seen. A piece of wood was indeed removed from the eye surgically, and, on questioning, the patient admitted that instead of striking only the lumps of coal he might have struck the wooden box in which they were stored. (2 figures.) F. Herbert Haessler.

Schmidt, Martin. **The operative treatment of corneal wounds.** *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 410-421.

The usual treatment of corneal laceration or perforation is to cover with a conjunctival flap. Direct suture is more difficult and takes longer to heal, but it is worthy of more extensive application to those wounds which are irregular and extensive. Suturing makes exact coaptation of the wound edges possible, and in cases where the iris is intact it makes healing possible without anterior synechia and with preservation of a normally functioning pupil. In a series of 32 cases only two eyes were enucleated and in many useful vision was retained. (1 table, 10 figures, references.)

F. Herbert Haessler.

Shershevskaya, O. I. **Ocular-fundus lesions in war injuries.** *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 31.

The most common choroidal ruptures are polygonal. Holelike ruptures are seen mainly in the macula. In

dimensions they vary from punctate ruptures to those involving one half of the fundus. Hemorrhages may accompany them: these are very slowly absorbed and can be seen months afterward. When the rupture spares the outer layers of the choroid its color is yellowish it is relatively small, slitlike, or sickle-shaped, with indistinct margins and usually nonpigmented. The complete ruptures, in addition to the white color of the visible sclera, show more intensive pigmentation. Ruptures close to the optic nerve may simulate myopic changes. When in the periphery the chorioretinitic changes may simulate nontraumatic lesions. Among secondary changes may be observed an ascending atrophy of the optic nerve and a degenerative maculitis. One extremely rare case presented detachment of the pigment epithelium, in the form of a markedly depigmented disc surrounded by a dark brown ring the inner border of which was serrated and obviously elevated, while the outer border of the ring was on a level with the rest of the fundus. Retinal ruptures are considerably rarer, and are mostly in the macula, but occasionally peripheral. In the macula they sometimes simulate Kuhnt-Junius macular degeneration. They very rarely result in detachment, and heal readily with scar formation even when large. There is also marked polymorphism of macular lesions, which vary from disappearance of the physiologic foveal reflex, and macular discoloration, to large macular holes. In addition to occasional optic-nerve atrophies, three avulsions of the optic nerves were observed. All three cases were accompanied by enophthalmos and disturbed motility of the globe. The same polymorphism noted before was observed in connection with fixed and floating vitreous opaci-

ties. Occasionally an opacity would be so brightly colored as to suggest a foreign body. M. Davidson.

Shershevskaya, O. I. Physiotherapy in war injuries of the eyes. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 27.

The conditions most responsive to physiotherapy have been hemophthalmos, traumatic iritis and iridocyclitis, and injuries of the lids and neighboring parts. Hemophthalmos was favorably influenced by diathermy with subsequent iodine iontophoresis, or by galvanic ion-diathermy with iodine. Diathermy treatments of two courses of two weeks each, with an interval of two weeks between, usually seemed to help in clearing up the vitreous. Iritis and iridocyclitis have benefited considerably from galvanic ion-therapy with adrenalin or atropine (depending on indications) combined with erythema doses of ultraviolet or ultrashort-wave therapy. Suppurative wounds and hypertrophic scars of lids and adjacent parts were benefited remarkably from paraffin therapy. Paraffin can be raised to a temperature of 70 to 75 degrees C. Because it retains heat and gives it up slowly and uniformly it does not harm tissues, and its heat penetrates deeply without dilating the surface vessels. A protective plate is placed under the lids to prevent injury to the globe, and care is taken that no water drops are mixed with the molten paraffin as otherwise a burn will result. The paraffin is applied for one hour 20 to 30 times.

M. Davidson.

Tikhomirov, P. E. Salvaging the war blind. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 10.

Perforating eye injuries are the most common of all injuries in war time

and are more serious than those of peace time. They account for most of the war-blinded. Blindness resulting from eye contusions is much less frequent. In the statistics of some hospitals bilateral eye injuries are as high as 15 percent. Many of these war-blinded can be cured. The four groups in which restoration is possible are those with traumatic cataract, corneal opacities, detachment of the retina, or hemophthalmos. In the author's material, all the traumatic cataracts were the result of perforating injuries and two thirds of them were found in the only remaining eye; but only 17 of them were free from complication by other lesions. The extractions were done within one to two months in most cases, and the results do not justify the traditional practice of waiting 6 to 12 months. There is no hurry when the other eye is normal. Special care to insure results is imperative in the one-eyed. Preliminary sterilization of the conjunctival sac is necessary, and the older methods, with mercury oxy-cyanide, collargol, and quinine, were found superior to streptocide or albucid. Complete anesthesia and akinesia are necessary. The corneal section is done with a small conjunctival flap and keratome, and is enlarged with scissors when necessary. Capsulotomy is done with capsule forceps rather than with cystotome. The lens matter, often sticky, is removed with a grooved spatula aided by pressure with Daviel's spoon. The rare vitreous presentation is controlled with a conjunctival suture. Occasionally a foreign body has to be extracted from the vitreous with the electromagnet after the cataract extraction. Nonmagnetic foreign bodies have been left alone without any ill results after two years of observation. The results

of extraction are good in a majority of the cases. In one case retinal detachment followed extraction. The majority of the corneal-scar group was complicated by secondary glaucoma difficult to combat. The best results were secured from Vogt's diathermy coagulation. Keratoplasty was done in ten cases with meager results. The prognosis in operations for detachment were found best when no proliferating retinitis was present. The results in hemophthalmos cases were not encouraging, probably because the material was too old at the base hospital for successful treatment. In conclusion the author points out that one has to take a chance in cases which would be turned down in peacetime.

M. Davidson.

Vancea, P. **The retinal hemorrhages of the new-born.** *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 272-274.

The author systematically examined the eye grounds of 253 new-born babies delivered in obstetrical hospitals in which the best care was assured. Retinal hemorrhages were found in 27 cases (11.8 percent), 18 bilateral, 11 unilateral. In only 9 of these was premature rupture of the membrane observed. In all cases the mother's pelvis was narrow. In one case delivery was accomplished by abdominal Cesarean section. The hemorrhages often absorbed within 10 to 12 hours, usually within two or three days, in eight cases within one week, in one case within two weeks. The author believes it possible that there may be a causal connection between retinal hemorrhage of the new-born and certain amblyopias (strabismus), and also of Coats's retinitis exudativa.

F. Nelson.

Yuzefova, F. I. **An evaluation of the results of surgical and conservative**

treatment of perforating injuries of the eye. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 24.

Since there has been some discussion recently as to the value of Kuhnt's conjunctival keratoplasty in perforating eye injuries in war, the author surveyed the results in one hospital where a series of 70 cases in 1940 and 1941 had been handled conservatively, that is without resorting to keratoplasty, and another series of 70 cases in 1942 and 1943 had been handled surgically. To make the two series comparable, cases with intraocular foreign bodies were excluded. The first series showed 14 enucleations, 16 cases with vision worse as end result, 22 blind as end result; while in the second series only 6 enucleations were found necessary; only 6 resulted in blindness, and none showed vision made worse. The author therefore advocates Kuhnt's operation. But preliminary care of the wound should include excision of prolapsed tissue, and use should also be made of galvanocautery, sulfidine powder, and retrobulbar anesthesia.

M. Davidson.

SYSTEMIC DISEASES AND PARASITES

Friedrich, W. M. **Ocular tuberculosis in its relation to the body as a whole.** Supplement 11, *Klin. M. f. Augenh.*, 1942, Supplement 11, 126 pp.

Over 2,000 patients with ocular tuberculosis have been cared for at the institute at Höchenschwand. After the first 500 had been seen the staff at the institute was in a position to investigate and treat all the clinical material on the basis of a unified point of view. The author suggests that in all previous literature on tuberculosis it has been assumed that after an initial attack of tuberculosis in an organ all

subsequent activity of the lesion takes place in the same organ without involvement of other organs. This conception is fundamentally false. The author conceives tuberculosis as a lymphohematogenous infection which becomes manifest now in one organ and now in another. Tuberculosis is not a disease that occurs in one or more attacks, but extends over decades, sometimes throughout an entire life.

All episodes of illness of possible tuberculous etiology in the patient's history must be justly evaluated in relation to the entire picture. To make this clear the author analyzed the records of over 1,500 patients. The largest number of them were between 30 and 40 years of age, because the patients were drawn from a group of industrially insured persons. One quarter of them had iridocyclitis, and patients in whom the ocular lesions were uveal—that is, iritis, choroiditis, endophthalmitis, or generalized uveitis, constituted 705 of the total number. (Bibliography.)

F. Herbert Haessler.

Klar, R. On dentogenous focal infection in ocular inflammation. *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 159-165.

The author presents a rather skeptical discussion of the importance of apical dental lesions in ocular infections. His own material consists of 155 patients with ocular infections, of whom 120 or 77 percent had dental infections which in the opinion of workers in the University Dental Clinic were potential foci of infection. In 98 patients or 63 percent the dental lesion was the only potential focus found. To provide a control series the author induced the dental clinic to examine the teeth of 155 entirely nor-

mal individuals and found that 100 of them or 64 percent had similar dental lesions. (Bibliography.)

F. Herbert Haessler.

Suurküla, J. Eye diseases caused by the larva of diptera (ophthalmomyiasis). *Klin. M. f. Augenh.*, 1942, Supplement 13, 40 pp.

In this monograph the author reviews systematically the information recorded in 132 communications in the literature. In primary ophthalmomyiasis the larvae from flies belonging to the following families have been found: Tachinidae, Sarcophagidae, Calliphoridae, Oestridae, *Castrophilida*, and Phocidae. In the conjunctival sac the commonest larvae are those of *Oestrus ovis*. In the lids the larvae found in the majority of cases were *Dermatobia cyaniventris* and *Wohlfahrtia magnifica*. The same two larvae have been repeatedly extracted from the orbit, to which they probably gained access through the mucosa at the internal angle.

Thirty cases of intraocular larval invasion have been recorded. Hypoderma was the common genus, much more rarely *Wohlfahrtia magnifica*. It is highly probable that in cases where the latter larva was reported the diagnosis was erroneous, since this organism is very poorly adapted for intraocular parasitism. However, the presence of numerous larvae of this species, as well as of *Sarcophaga carnario* and *Calliphora vomitoria*, in ulcerated fistulous partially destroyed globes has been unquestionably observed. Most cases of ophthalmomyiasis are reported from southern countries. In northern latitudes infection is predominantly with *Hypoderma*, and is most common near the coast. This is the fly that causes most of the cases of ophthalmomyiasis interna. The

periodicity in the occurrence of morbid manifestations is ascribed to the gradual development of anaphylactic reactions. Inoculation presumably occurs when the adult fly in flight deposits its eggs on the surface of the tissue. Very malignant and generalized larval invasions occur only in decrepit individuals and in bodies with considerably reduced resistance. (2 tables, 12 figures, 2½ pp. bibliography.)

F. Herbert Haessler.

Szinegh, Béla. Parenteral liver injections in the diagnosis and treatment of tuberculous eye diseases. *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp. 166-172.

A patient who has tuberculosis and who does not react to intradermal injection of tuberculin is said to be in an anergic state. This is not advantageous from either the diagnostic or the therapeutic point of view. The patient is unable to produce antibodies and the injection of tuberculin is useless. The author describes the clinical course of five patients in whom parenteral injection of a liver preparation made for treatment of pernicious anemia was effective in "disanergizing" the body. The preparation (Perhepar) is used intramuscularly twice daily for a week. The liver extract produces a reticulocytic crisis. Normal control individuals remain inactive to tuberculin injection after repeated injections of liver extract. (References.)

F. Herbert Haessler.

Wegner, W. Difficulties in differential diagnosis of ocular tuberculosis. *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 337-348.

Since it is becoming clear that tuberculosis is the most important etiologic factor in chronic inflammatory lesions

of the interior of the eye, its importance in differential diagnosis can hardly be overemphasized. To clarify the difficulties the author records over a dozen case histories, rather briefly though in adequate detail, and discusses each. Diagnostic errors that were made because of possibly faulty examination or inadequate analysis of facts do not form part of this study. Errors may be made by dismissing too readily the importance of a personal and family history, but also by laying undue stress on these data. In three cases a sympathetic ophthalmia had been wrongly diagnosed elsewhere as tuberculosis, and in several cases a chronic internal irritation caused by an intraocular foreign body was not suspected until signs of siderosis appeared. In one case of severe bilateral intraocular inflammation in a patient who was neither underweight nor febrile, the correct diagnosis was not made until autopsy revealed a most extensive tuberculosis of all the thoracic and abdominal lymph nodes. The patient died of amyloidosis of the kidney. Atypical trachoma and syphilitic lesions of the eye may lead to serious diagnostic difficulties. In a young man of 26 years with extensive bronchial carcinoma and metastasis to the vertebrae, liver, and eyes, no etiologic diagnosis was made by either internist or oculist. After displaying this small collection of diagnostic difficulties the author is disposed to humility. (References.)

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Csapody, Istvan. The professional life of the ophthalmologist. *Klin. M. f. Augenh.*, 1942, Supplement 10, 92 pp.

This well-written, readable pamphlet is presumably addressed to medical students and recent graduates who might consider preparing themselves for the practice of ophthalmology. The author describes (1) the characteristics of mind, body, and temperament that best fit a man for the specialty; (2) the course of training which will fit a candidate for surgery and consultation practice; (3) the daily routine of the eye doctor in clinic, private consultation room, hospital and surgery; (4) the person-to-person relationship between doctor and patient when preparing the patient mentally for operation or for impending blindness; and (5) the ophthalmologist's duties in giving expert opinion on matters of compensation and litigation.

F. Herbert Haessler.

Kravkov, S. V. Jan Purkinje and ophthalmology. *Viestnik Oft.*, 1944, v. 23, pt. 5, p. 3.

On the occasion of the 25th anniversary of the death of Czech scientist Purkinje, attention is called to his three great contributions to the physiology of vision. It is pointed out that the reflex images of the lens were described by him in 1825, and were later (1837) applied by the Frenchman Sanson in diagnosis; and were still later utilized by Helmholtz, who measured the changes in size of the images, in developing his theory of accommodation. The second important contribution was the construction in 1823 of the first perimeter, accompanied by many practical suggestions on performing perimetry. Aubert and Foerster to whom the first perimeter is usually credited did not act until 1857. The third very important contribution, known as the Purkinje phenomenon, and consisting in blue ap-

pearing much brighter than red in twilight, laid the foundation for the duplicity theory of Kries, and was utilized by Kravkov in exploration of dark adaptation. Other contributions of Purkinje deserving mention are his discussion of positive afterimages of the complementary color, of phosphenes from pressure and electric stimuli, of methods of entoptic examination of the retinal vascular network (which later (1872) enabled Mueller to determine the position of the pericipient layer of the retina and identify it as the layer of rods and cones), of the effect of belladonna on the eyes, of the possibility of voluntary unilateral adduction of an eye while the other is stationary, and of the physiologic substratum of sleepiness being referred to the eyes. Attention is also called to Purkinje's activities as a Czech patriot struggling against the German-Austrian oppression of his days.

M. Davidson.

Lisch, Karl. Sterilization and success of treatment in serious hereditary eye diseases. *Klin. M. f. Augenh.*, 1941, v. 107, Nov., pp. 521-526.

Reply to the critical article of R. Schmidt (see below) concerning the author's previous article on this theme. Lisch insists that it is not permissible to allow reproduction by individuals suffering from hereditary cataract of any type. "He who is doing race hygiene must never think therapeutically but only heredobiologically." It does not matter that a condition can be completely repaired, either surgically or otherwise. It is the task of a race-conscious physician to eliminate the genotype from reproduction even if the phenotype can be rendered practically normal by therapeutic means. As to the question of elimination of more or

less serious refractive errors he feels that our knowledge of the mode of inheritance of such errors is not yet broad enough to justify sterilization in such cases, unless the condition renders the patient practically blind for distance as well as for near and at least one other such case in the family is known. (References.)

F. Nelson.

Mills, E. T. Medical social work in sight conservation as developed in the State of Washington. *Sight-Saving Review*, 1944, v. 14, Winter, p. 170.

The author describes the plan of sight conservation used by the Department of Social Security, and brief individual case records show some of the end results. Francis M. Crage.

Nuri Fehmi Ayberk. Review of the history of Turkish ophthalmology from the nineteenth century to the present. *Göz Klinigi*, 1945, v. 2, no. 5, pp. 119-122; and no. 6, pp. 145-150.

In 1839 under the reign of Sultan Mahmoud II, there was inaugurated a school of medicine (at first called "justice," then "military"), directed by a Viennese physician, Dr. Bernard, in the same location as the present Galata Saray Lyceum. The teaching of ophthalmology began in this school in 1853. The official Chair of Ophthalmology was established in 1870, and was committed to Colonel Ilya Abdunnur, who had taken his training in France. Upon his death he was succeeded by Major Essad (1895), who also had specialized in Paris. In the same period a certain Behdjet taught ophthalmology to the civil medical school. In 1908, when the two schools were combined to form the faculty of medicine, General Essad and Dr. Ziya, who had studied in Germany, were ap-

pointed professors simultaneously. The first eye clinic in Turkey was inaugurated at the Military School of Medicine of Demirkapou in 1895, with Professor Essad. The previous teaching had all been theoretical.

Apart from the teaching in the military and civil schools of medicine, the Military Hospital of Haydar Pasha (1871 to 1900) and then the Military Hospital of Gulhané (1900 to 1945) were two centers where it was possible to specialize in ophthalmology. Two eminent teachers, one at the Military Hospital of Haydar Pasha, Colonel Dikran Adjemyan (1875 to 1908), and the other at the military school and Hospital of Gulhané, General Niyazi Ismet Gözcü (1909-1944), showed great scientific activity, especially the latter, who trained a considerable number of distinguished oculists. (3 photographs.)

Prelat, P. Ophthalmology in Paris during the war. *Amer. Jour. Ophth.*, 1945, v. 28, Oct., pp. 1088-1111.

Schmidt, Rolf. The question of sterilization of persons with "inherited cataract." (Reply to article by Lisch.) *Klin. M. f. Augenh.*, 1941, v. 107, July, pp. 67-72.

In contrast to Lisch (*Amer. Jour. Ophth.*, 1942, v. 25, p. 127), who, literally following the Nazi law of elimination by sterilization of all persons who might transmit hereditary disorders, regardless of whether or not they were curable, Schmidt advocates sterilization of all persons with "hereditary cataracts." Although advocating elimination of persons with so-called complicated cataracts, he is opposed to sterilization of persons suffering from noncomplicated simple cataracts. In this connection cataracts are to be re-

garded as complicated when the carrier is either himself mentally or physically inferior or belongs to a family the members of which frequently have cataracts complicated with such other defects as lack of foveal function, nystagmus, and additional physical or mental malformations which, according to experience, cannot be treated successfully by operation or other means. Schmidt argues consequently that higher or even medium refractive errors which render the bearer "practically blind" without therapeutic procedures (that is, corrective glasses) would have to be eliminated too, since many of these refractive errors are also inherited. ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Balado, M., and Fortin, E. P. Regional anatomy of the fibers of the macular area. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, May, pp. 245-265.

In this article the authors study and discuss the course and arrangement of the retinal fibers, particularly those of the macular region, by means of entoptic observation and histologic preparations. The article does not lend itself to abstracting. (17 illustrations.)

Plinio Montalván.

Vidal, F., and Malbrán, J. Arrangement of the peripheral nasal bundle in the human chiasm. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, July, pp. 339-345.

In a specimen from a case of optic atrophy of the left side the authors studied the arrangement of the peripheral nasal fibers in the chiasm. In the sagittal section it was observed that the lamina supraoptica divided the upper

aspect of the chiasm into an intraventricular and extraventricular portion. The nasal peripheral bundle occupied the extraventricular portion and was in close relation with the cisterna chiasmatica. In the specimen under study the bundle ran from right to left and from above downward, occupying the anterior knee of the chiasm and invading the optic nerve in an extension of approximately 500 microns, where it occupied the inner and lower aspects. This arrangement explains the prechiasmal thickening clearly seen in the sagittal section. In the two posterior thirds of the chiasm the fibers under consideration occupied the external border. (5-photomicrographs, references.) Plinio Montalván.

Vidal, F., and Malbrán, J. Studies on the chemical composition of the aqueous humor of the cat. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, May, pp. 231-237.

In this article, the second of a series on the subject, the authors describe their procedure for obtaining samples of aqueous humor and the analytical methods followed for quantitative determination of sodium, chlorine, ascorbic acid, total nitrogen, nonprotein nitrogen, proteins, water and ashes, glucose, and pH. The article does not lend itself to abstracting.

Plinio Montalván.

Vidal, F., and Malbrán, J. Studies on the chemical composition of the aqueous humor of the cat. 3. Sodium and chlorine. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, June, pp. 299-310.

The authors determined the contents of sodium and chlorides in the aqueous humor of the cat. They present their figures in tabulated form and compare

them with those found by other observers. The article does not lend itself to abstracting. (4 tables, references)

Plinio Montalván.

Vidal, F., and Malbrán, J. Studies on the chemical composition of the aqueous humor of the cat. 4. Protein and nonprotein nitrogen, water, and ash. Arch. de Oft. de Buenos Aires, 1943, v. 18, July, pp. 345-355.

The authors present in tabulated form the figures for protein and nonprotein nitrogen, water, and ash in the aqueous humor of the cat. The values for protein nitrogen in the primary aqueous are considerably higher than those reported by other observers. The

marked increases found by the authors in protein content in the secondary or plasmoid aqueous agree with the figures published by previous observers. The changes which the endothelial barrier undergoes after paracentesis of the anterior chamber and the formation of plasmoid aqueous are strong points in favor of the theory which considers the aqueous as a dialysate. The figures for nonprotein nitrogen are comparable to those of other observers and the proportions of nonprotein nitrogen in aqueous humor and blood found by the authors are similar to these obtained by Krause and Yudkin in the dog. (6 tables, bibliography.)

MISCELLANEOUS

Members of the San Antonio Ophthalmological Society conferred with military medical men November 13th at the Army Air Forces School of Aviation Medicine, Randolph Field, Texas, on methods of combating eye, ear, nose, and throat diseases.

Members of the teaching staff of the military installation discussed the utilization of new drugs in the prevention and control of ophtho-otolaryngologic diseases. Displayed at the conference were medical photographs and art work pertaining to eye, ear, nose, and

throat diseases. The program also featured a demonstration of a new magnetic wire recorder by Major Hubert B. Peugnet, Saint Louis, Missouri, which is used in research studies in the AAF School of Aviation Medicine Department of Otolaryngology.

Brig. Gen. Eugene G. Reinartz, Commandant of the School, welcomed the Society to the facilities of the research laboratory following a reception and dinner at the Randolph Field Officers Club.

Lt. Col. Brittain F. Payne, New York City, and Captain Fred W. Ogden of New Orleans, Louisiana, assisted Drs. Virgil S. Steele and Dan Russell of San Antonio in organizing the program.

The following courses will be given by the Harvard Medical School: March 4 to April 27, 1946—Basic science in ophthalmology; April 29 to May 25, 1946—Clinical ophthalmology; and May 27 to June 22, 1946—Fundamentals in refraction. These courses are being given at this time particularly for the men returning from the Armed Forces.

At the postgraduate courses given by the University of Buffalo School of Medicine, Dr. Walter F. King, Associate Professor of Ophthalmology, lectured on "Office management of injuries, foreign bodies, and infections of the eyes."

SOCIETIES

The officers of the Brooklyn Ophthalmological Society for the year 1945-1946 are: Dr. Michael J. Buonaguro, president; Dr. Benjamin C. Rosenthal, vice-president; Dr. Louis Freimark, secretary-treasurer; and Dr. George A. Graham, associate secretary-treasurer.

The Mississippi Valley Medical Society is resuming its annual essay contest, which has not been held during the war. In 1946 it offers a cash prize of \$100.00, a gold medal, and a certificate of award for the best unpublished essay on any subject of general medical interest (including medical economics) and practical value to the general practitioner of medicine. Certificates of merit may also be granted to the physicians whose essays are rated second and third best. Contestants must be members of the American Medical Association who are residents of the United States.

Contributions should not exceed 5,000 words, be typewritten in English in manuscript form, submitted in five copies, and must be received not later than May 1, 1946.

Further details may be secured from Dr. Harold Swanberg, secretary, Mississippi Valley Medical Society, 209-224 W.C.U. Building, Quincy, Illinois.

At the regular meeting of the Brooklyn Ophthalmological Society, held on December 20th, the following scientific program was given: "The so-called demyelinating diseases of the nervous system and their relationship to ophthalmology" by Dr. A. M. Rabiner, and "Arachnoiditis" by Dr. Daniel Kravitz, dis-

cussion by Dr. E. Jefferson Browder.

At the meeting of the Milwaukee Ophthalmic Society which was held on November 27th, Dr. S. S. Blankstein presented a paper on "Surgery of the lacrimal apparatus."

PERSONALS

Lt. Col. M. E. Randolph (MC), Chief of the Eye, Ear, Nose, and Throat Section at Valley Forge General Hospital, was transferred to the Office of The Surgeon General, Washington, D.C., to serve as Chief Consultant in Ophthalmology to the Surgeon General. He will be replaced by Lt. Col. Philip Thygeson (MC).

TECHNICAL REFINEMENTS IN THE REMOVAL OF MAGNETIC
FOREIGN BODIES FROM THE POSTERIOR SEGMENT
OF THE EYE*

GILBERT C. STRUBLE, LT. COL. (MC), A.U.S.

AND

LEO J. CROLL, CAPT. (MC), A.U.S.

Cleveland, Ohio

It is not the purpose of this paper to discuss the advantages or disadvantages of posterior-route extraction of metallic foreign bodies as compared to the anterior route. All authorities will agree that, in many instances, removal of foreign bodies by the posterior approach is essential. The surgical technique, experimental data, and clinical reports to be presented were for the most part accomplished with the small hand magnet.[†] The reason for this was twofold: 1. This particular magnet is the standard item of issue in Army hospitals.[‡] 2. This magnet is of the type and size in the possession of most ophthalmologists.

The military ophthalmologist has had occasion to see many patients with retained intraocular foreign bodies. In the majority of cases, our experience has shown these retained fragments to be very small, usually 1 mm. or less in size. This was in part due to the following factors: 1. The larger particles had been removed overseas. 2. Many of the eyes receiving penetrating injuries by larger fragments

had been destroyed or so seriously damaged they had been enucleated before the patient arrived at the Eye Surgical Center in the Zone of the Interior.

Some of these very tiny fragments were picked up by the use of specialized X-ray techniques. Recently we had two or three cases in which a very small particle could be seen with the ophthalmoscope floating free in the vitreous, although the most painstaking X-ray technique showed no foreign body whatsoever. Such minute particles, if magnetic, can be successfully removed.

The retained intraocular metallic foreign bodies encountered in the majority of cases seen in an Eye Surgical Center, have been present from two weeks to two or three months—not because the diagnosis has been missed, but rather because the patient had incurred other multiple serious wounds threatening to life for which other major surgical procedures had, of necessity, been required. Some of these eyes required immediate enucleation. Many, however, were in good condition. It was not unusual to find an eye with single or multiple retained intraocular foreign bodies with a vision of 20/20 and very little or almost no ocular reaction present. This is not surprising

* From the Eye Surgical Center, Crile General Hospital.

† Lancaster model with foot switch.

‡ Giant magnets are also available in Army Eye Surgical Centers.

when one considers that these patients received the attention of a well-qualified ophthalmologist almost from the first hour of the original injury. Any necessary emergency eye surgery had been accomplished immediately, with careful follow up of the case through the chain of evacuation.

In September, 1942, one of us* reported an aid in the precise localization of metallic foreign bodies embedded in the choroid and retina. In this case an officer patient was found to have a 1 by 1 by 1-mm. retained metallic foreign body embedded in the choroid and retina of the left eye, $4\frac{1}{2}$ mm. from the optic disc, in the superior nasal quadrant. The vision of the eye was 20/20. The vitreous was clear except for a few red blood cells, and very little local ocular reaction was present. The injury had been incurred five days prior to the time first seen. Because the eye became irritable and photophobic, with an increasing number of cells in the anterior segment and vitreous, the removal of the particle was thought to be imperative. The operative approach in this case called for a pinpoint localization in order to make the scleral incision directly over the retained fragment. It was believed that such an approach was indicated to prevent lateral drag on the choroid or retina, as would have been the case had the magnet been applied at a point on either side of the fragment. At the time of surgery a previously prepared lead marker affixed to an ordinary black-silk suture was sewn to the sclera at the point indicated by the X-ray localization.

The internal rectus muscle, which had been detached, was reattached with one suture and a PA and a lateral X-ray film was made in the operating room with the portable X-ray machine. It was evident

from the PA film that the foreign body had been missed 4 mm. in the vertical plane, and from the horizontal film that an error of 3 mm. in the anterior-posterior direction had been made. It was a simple matter to make the correction indicated from the known location of the lead marker and to cut down directly upon the foreign body, which was removed on the first application of a small hand magnet. Convalescence in this case was uneventful, with no evidence of vitreous hemorrhage, further damage to the retina or choroid, or late sequelae. Following this experience it became our custom to utilize a lead marker on the sclera in the majority of those cases wherein a posterior approach was indicated. This was in no way a reflection on the ability of the roentgenologist who had performed the localization. As a matter of fact, in our experience, it is often extremely difficult to mark on the sclera the exact site of the X-ray localization of the foreign body. This is due, in part, to the difficulty of picking the exact meridian indicated, and is especially true if the fragment is far posterior, and when the globe must be strongly pulled to one side. We have also found this aid in localization of great value in those cases in which the exact position of the particle was in doubt. We refer especially to those instances wherein repeated localizations may possibly vary, by one or two millimeters, but wherein this error may place the particle either in or out of the globe. Such a marker can be quickly and easily fashioned by shaving a piece of lead with a sharp knife so as to secure a fragment approximately $2\frac{1}{2}$ by 2 mm. in size. This lead fragment is fastened around and pinched on to a silk suture attached to a scleral needle. In any case the size of the marker should be distinctive and of a size differing from that of the retained intraocular foreign

* Gilbert C. Struble, read before the Indianapolis Ophthalmological Society.

body so that no confusion will arise in viewing the film taken in surgery with the portable machine as to which is the marker and which is the foreign body.

Such a procedure will, to some extent, prolong the operating time. This can, however, be kept to a minimum if a portable X-ray machine is available when needed and if rapid developer solution is used. Some additional minutes are lost in redraping the patient following the taking of the X-ray pictures during the operation, but we have found the procedure well worth the time required.

For a time we experienced difficulty in maintaining the sterility of sutures and needles attached to a resected ocular muscle during the taking of the additional films. This difficulty was solved by placing the sutures in a sterile test tube anchored to the upper lip and below the nose with a strip of adhesive plaster. Sterility of the field is maintained by placing the cassette under a sterile towel.

At the present time we have added other steps to this procedure, some of which are original and some a variation of other methods. Lancaster¹ described a modern diasclear method of extraction of foreign bodies. He advocated a scleral incision by layers with the diathermy knife, to avoid hemorrhage. He described the application of the tip of the hand magnet to the incision with extraction of the foreign body without entering the vitreous. He states the cutting current of the diathermy knife should not be allowed to act on the vitreous but does not state whether the uvea is actually penetrated and included in the section with the knife.

Verhoeff² advocates a careful scleral section under a conjunctival flap 5 to 6 mm. from the limbus and parallel to the ora serrata. He used a large knife needle, the point of which had been filed off. A careful dissection down to the ciliary

body is made, great care being taken not to penetrate this tissue with the knife. The tip of the large hand magnet is applied to the operative wound so as to pull the fragment through the ciliary body. Verhoeff states that if the foreign body is small a small cut in the ciliary body may be required to facilitate its delivery.

The following technique has, in our hands, been so uniformly successful that we feel it is worth describing in sequence.

I. PINPOINT LOCALIZATION OF THE FOREIGN BODY AS AFOREDESCRIBED. (figs. 1-6). This is essential where the foreign body is embedded in the choroid and retina: (a) To prevent lateral drag on the choroid and retina, or grooving and guttering of these layers when removal of the foreign body is attempted from one side or the other. (b) To keep choroidal or retinal bleeding to a minimum or prevent it entirely. (c) To reduce postoperative reaction and prevent late sequelae such as retinitis proliferans and retinal detachment.

II. FIXATION OF THE GLOBE, BY SCLERAL SILK SUTURES. ONE ON EITHER SIDE OF THE SCLERAL SECTION. The following advantages have been experienced: (a) Complete control of the operative area is maintained constantly. (b) Any desired amount of traction on the lips of the scleral section can be maintained during the section without instrument manipulation of the margins of the incision, and the attendant danger of nicking or penetrating the choroid or ciliary body, which is to be avoided at all cost. (c) Any desired degree of scleral separation can be maintained during the extraction of the foreign body without the use of instruments, and the operative site can be guided to the tip of the gaint magnet on those rare occasions when such an instrument is needed. (d) The sutures

are available and ready as additional supporting sutures if desired for closing the sclerotomy incision, and as a guide suture during the application of the diathermy barrage.

III. THE SCLERAL SECTION. Using a loup, a brilliant source of light, and a cataract knife, we make a 6-mm. scleral

Fig. 3 (Struble and Croll). Lateral position. The cassette is under a sterile towel.

section between the scleral retraction sutures (see II). The sclera is carefully divided by layers until approximately four fifths of the thickness of the sclera has been traversed. At this point a doubled-armed, 000 plain catgut mattress suture is placed through one side of the scleral incision, involving one half of the thickness of the sclera. These sutures are carried through the opposite lip of the section and through the outer one half of the thickness of the sclera. One tie is made in the suture, which is left loose and drawn away from the site of the incision. This suture is for later approximation of the scleral section after the foreign body has been removed. The incision is now completed down to the choroid, or pars plana of the ciliary body,

great care having been exercised not to perforate or penetrate the uvea. By lateral traction on the scleral lips with the retraction sutures, this dissection is accomplished with reasonable care, and is continued until all of the scleral fibers overlying the uvea are completely cut through. We have found that as soon as a small black glistening uveal bead presents in the section the remainder of the uveal exposure can be facilitated by inserting the blunt tip of a pair of conjunctival scissors and dividing the few remaining scleral fibers with a single cut. The blunt back side of the lower blade of the scis-

Fig. 5 (Struble and Croll). The arrow indicates the lead marker and an error of 6 mm. in the lateral meridian.

procedure a black bead of choroid (or ciliary body, if the pars-plana route is being used) presents between the margins of the incision. When the approach is made posteriorly over the choroid, the scleral section should be made in the antero-posterior meridian. When the pars-plana approach over the ciliary body is utilized the section should be made from

Fig. 6 (Struble and Croll). The arrow indicates the retained intraocular foreign body and the lead-plate marker. There is less than 1 mm. of error in the vertical measurement.

sors is used to push the uvea away from the scissors tips.

The section is now complete. Any bleeding encountered during this dissection is readily controlled by coagulation of the vessel with the diathermy tip, which should always be available both for the purpose of hemostasis and later for the diathermy barrage around the operative site, when indicated. At this step of the

6 to 8 mm. from the limbus, concentrically, and parallel with the ora serrata.

IV. REMOVAL OF THE INTRAOCULAR FOREIGN BODY WITHOUT PENETRATING THE CHOROID OR THE PARS PLANA OF THE CILIARY BODY WITH THE MAGNET TIP. The broad tip of the small hand magnet is placed in contact with the uvea. This particular tip was especially designed by Lancaster³ to give the strongest possible pull on a fragment at a distance. "The blunter and shorter the pole, the stronger the pull when tested at 20 mm. or more."

It has been found that the 6-mm. incision that has just been described is adequate, so that a considerable area of the magnet tip is in contact with the surface of the uvea. The foot switch is now closed and the foreign body drawn through the retina and choroid, or the pars plana of the ciliary body. This is possible because of the well-known fact that a metallic foreign body always approaches the magnet point first. It, therefore, acts as its own perforator and will emerge through the intervening tissues, making the smallest opening compatible with its size. In no event is it necessary to insert the magnet tip into the vitreous, even for extremely minute fragments. This is well demonstrated in the experimental work to be described. Particles over 0.5 mm. in size, if accurately localized, have sufficient impact cleanly to perforate the choroid and retina or pars plana, usually on the first application of the magnet. Foreign bodies 0.25 mm. in size will present beneath the uvea but usually require a small nick in the uvea for their delivery. We believe that there are many advantages in not entering the vitreous with the magnet. The risk of infection is reduced to a minimum, and intraocular hemorrhage with the resultant formation of vitreous bands and late retinal detachment is also reduced to a minimum or prevented entirely. We feel

we can safely explore or attempt the surgical removal of fragments which have some indication of being very poorly, if at all, magnetic, and that we can assure the patient in advance that should removal prove unsuccessful his eye will have in no way been injured. This is especially important should the eye be quiet, the vision normal or nearly so, and where the foreign body appears to be aluminum, plastic, or some other substance well tolerated by the eye.

V. CLOSURE OF THE SCLERAL INCISION. Following removal of the foreign body the mattress catgut suture, previously placed, is tied. This securely approximates the scleral margins. The silk retraction sutures on either side of the section are now removed or they may be tied together over the section as a supporting suture. They may temporarily be left uncut to act as a guide suture to be used in manipulating the globe during the last procedure; namely,

VI. THE DIATHERMY BARRAGE AROUND THE OPERATIVE SITE. Since the retina is in contact with the choroid, we have carried this barrage through only the outer two thirds of the sclera so as not to injure the underlying retina with the diathermy tip. If desired, surface scleral coagulation with the small ball electrode may be substituted, but care must be taken not to burn the sutures.

EXPERIMENTAL

FOREIGN BODIES FREE IN THE VITREOUS

In following these six steps, and using precise localizations with the lead-plate technique, it began to appear that almost all magnetic foreign bodies encountered in clinical work could be successfully removed with the small hand magnet alone. This included particles even as small as 0.25 mm. in diameter, provided the particle was within the "certain or critical zone" for its particular size. Obviously

a 0.25-mm. fragment, lying in the center of the vitreous 10 or 11 mm. away, cannot be reached with the hand magnet but may be reached with the giant magnet. We were, however, being confronted with an increasing number of foreign bodies free in the vitreous. It was felt that when possible, it was advantageous to remove these particles through the pars-plana approach instead of through a posterior sclerotomy over the choroid. This approach has the additional advantage that no penetration of the retina by the foreign body occurs, and for this reason any possibility of late detachment of the retina is reduced to a minimum. Immediately there arose the question as to what distances various-sized particles could be drawn through the vitreous and through the scleral incision.

The experimental work was performed with the use of particles of steel shavings measuring 1 mm., 0.5 mm. and 0.25 mm. in diameter, since these were the sizes most often encountered clinically. The work was carried out on eyes of freshly killed hogs, less than 12 hours dead, which were kept refrigerated until used. The small hand magnet with foot switch was used in all the experimental work for the reasons mentioned earlier in this paper. It is realized that many factors exist in these experiments not present in the injured human eye.

First the retina of the hog appears to be slightly thicker than that of man. Second, no organizing exudate, fibrin, or hemorrhage exists in the experimental specimens.

The vitreous in the fresh hog eyes grossly seemed to be of the same consistency as that of the human eye and was probably a negligible factor in error. Grossly, the choroid in the hog and human eye appeared to be almost identical in consistency and thickness.

The experiments were carried out as

follows: Scleral retraction sutures were placed as previously described about three sixteenths of an inch apart, and a scleral incision by layer dissection was made between the sutures down to the ciliary body or the choroid until the usual black bead presented. These sutures were then tied with one double tie so as effectively to close the incision temporarily during sectioning of the globe.

The eye was then turned on its side, and with a sharp cataract knife the entire anterior segment of the eyeball was cleanly and quickly excised on a plane just behind the iris. It was found that by utilizing a sharp knife and rapid section a negligible loss of vitreous occurred. The sectioned eye was again placed upright in the manikin, cut surface uppermost. The scleral silk sutures were untied, exposing the uveal bead as before.

The previously chosen, measured, and weighed metallic fragment was then inserted into the vitreous at varying distances from the scleral section, beginning on the side of the eye opposite the section. The blunt tip of the small hand magnet was applied in contact with the uveal bead and 10 consecutive tries for the foreign body were made; each consisted of five seconds' duration. In cases of failure the foreign body was removed from the vitreous and moved closer to the point of sclerotomy and another attempt at removal made. The distance in millimeters from the foreign body to the scleral section was carefully measured on each occasion prior to attempted removal. In each instance the foreign body was placed in the vitreous at a depth corresponding to that of the scleral section so that a straight pull with the magnet could be made on each occasion (figs 7-11).

The direct observation of metal particles in the vitreous under magnetic attraction proved to be very interesting. The foreign body would move toward the

Figs. 10 and 11 (Struble and Croll). Experimental specimens. Fig. 10 shows the metallic foreign body being introduced into the vitreous. The reflexes represent high lights on the vitreous. Fig. 11 shows the foreign body emerging through the choroid. The magnet tip is held at a distance from the incision to demonstrate this to better advantage.

magnet to some degree, regardless of the distance involved. When the distance was too great for removal it would at once return to its original position when the foot switch of the magnet was released. In some instances, following 10 magnet applications, the final resting position of the foreign body would be a little closer than it was in the beginning, but in most cases it would come to rest in its original position. The experimental data accumulated in this work are tabulated in the three graphs (figs. 12-14). Each graph has been divided into three zones: first, a "certain zone" representing that distance at which the foreign body was always secured on the first attempt at removal; second, a "critical zone," where the fragment was secured following multiple applications; third, a "failure zone," representing that distance at which removal was impossible. The "certain" and "critical" zones for each sized particle were plotted on schematic eyes. These zones represent those distances at which particles of this size, free floating in the vitreous, can be consistently removed by the use of the pars-plana approach. The distances illustrated can likewise be applied to the posterior approach over the choroid. This route would be indicated in those cases wherein the given-sized fragment occupies a position far posterior in the vitreous. In such a case it may no longer fall within the "certain" or "critical zone" whence removal is possible by using a pars-plana approach.

On many occasions when the foreign body was under direct observation in the "critical zone" it was noted that it would at times appear almost to touch or "nudge" the retina during the application of the magnet and then return to its original position as the foot switch was released. With the foreign body in the "certain zone" it appeared that the success

Fig. 13 (Struble and Croll). "Certain, critical, and failure zones" for magnetic fragment 0.5 mm. in size.

Fig. 14 (Struble and Croll). "Certain, critical, and failure zones" for magnetic fragment 1 mm. in size.

of the extraction on the first application of the magnet depended upon the initial impact of the foreign body against the retina and choroid and not upon any subsequent drag or pull on these membranes. This, we believe, is an important point, for the portal of exit of the fragments was very minute; so small, in fact, that it could not be seen afterward with the unaided eye and no late evidence of tension or traction on the uvea or retina could be made out. The 0.5- and 1-mm. fragment could always be delivered without difficulty. The 0.25-mm. fragments, apparently, as a result of their very small size and lack of impact, had to be aided in their path through the uvea by a very small nick with the tip of the cataract knife at the time they presented beneath these structures. In no instances were these fragments sharply pointed. They were, as a matter of fact, small square or oblong particles with blunt ends.

FOREIGN BODIES EMBEDDED IN THE RETINA AND CHOROID

In this series of experiments the hog eyes were prepared as before. The foreign body, however, instead of being planted free in the vitreous was now embedded in the choroid and retina at varying distances from the scleral section, and efforts at removal with the magnet were repeated in the usual manner. The series of experiments was inconclusive in so far as the ability to remove the foreign body at distances greater than 4 mm. was concerned. This was probably due to the fact that the fragment was not uniformly embedded in the choroid, retina, and the inner layer of the sclera in all instances.

One consistent fact stood out in this series. In those experiments where the fragment was pulled laterally for a distance of 3 or 4 mm. toward the sclerotomy opening and magnet, a tear or gutter of the retina or choroid was

created throughout the length of the movement of the particle.

In those cases, however, where the foreign body was embedded in the choroid or retina directly overlying the scleral opening, it was always pulled through by the magnet on the first attempt with a minimum of trauma to these layers. We feel this is another argument for precise pinpoint localization of metallic foreign bodies embedded in these structures at the time of surgical removal.

CLINICAL OBSERVATIONS

In the schematic eye represented below multiple metallic foreign bodies of indicated size are shown at the distances and in the zones in which their removal was accomplished. The diagram shows those

Fig. 15 (Struble and Croll). Schematic eye showing distances in millimeters in which metallic foreign bodies have been removed clinically. In no instance has the magnet tip penetrated the uvea.

foreign bodies removed over a three-months' period (fig. 15).

Those cases listed as pars-plana approaches and scleral sections over the choroid are grouped separately. These distances have been measured from lead-plate localizations made during the opera-

tive removal of the fragment. All of these particles were removed with the small hand magnet with a single exception. In this one instance a very minute metal fragment less than 0.25 mm. in size was localized and could be seen immediately behind the lens in the exact center of the globe. It was obviously outside the "certain or critical zones" for particles of its size. Repeated applications of the hand magnet produced no results. It was removed by a prolonged exposure (about three minutes) to the giant magnet.

In one case we misjudged the size of a fragment floating in the posterior vitreous and attempted to pull it forward through a pars-plana approach. The particle was so small it could not be visualized by the X-ray. We were unsuccessful both with the hand and the giant magnet. A posterior approach 10 mm. farther back over the choroid (and 10 mm. closer to the particle) resulted in prompt recovery of the fragment on the first application of the hand magnet. In every instance removal was accomplished without uveal penetration with the magnet tip. No instance of retinal separation, postoperative infection, or vitreous hemorrhage has occurred to date.

CONCLUSIONS

1. A method of pinpoint localization of metallic foreign bodies in the eyeball, using a small lead plate sewn to the sclera, has been presented.

2. The removal of magnetic foreign bodies in the posterior segment of the globe can be accomplished without penetrating the choroid or pars-plana with the magnet tip.

The success of this procedure depends on the following factors: (a). Pinpoint localization of the foreign body. (b). A painstaking layer dissection of the sclera between scleral retraction sutures until the black uveal bead presents in the section.

3. A simple method for fixation of the globe during the scleral section and removal of the foreign body has been described, together with a simple suture for closing the incision after the operation has been completed.

4. Retained intraocular magnetic foreign bodies down to and including particles 0.25 mm. in size can be consistently removed with the hand magnet, provided: (a) The foreign body has been accurately localized. (b) The fragment lies within the proper zone of action of the magnet.

5. Many cases of metallic foreign bodies free floating in the vitreous can be removed through a pars-plana approach providing the particles lie in the "certain" or "critical" zone as herein determined for its size and weight.

6. By referring to the tables and knowing the size of the magnetic foreign body in advance from the X-ray localization, the operator can choose with a considerable degree of assurance which operative approach will most likely give successful results.

THE OCULAR COMPLICATIONS OF LEPROSY*

JOSÉ MENDONÇA DE BARROS, M.D.†

São Paulo, Brazil

Traditionally, leprosy is dreaded as probably the most disfiguring of all diseases. It is also true, but not so generally recognized, that leprosy has a higher percentage of ocular involvement than any other systemic infection. When the threat of blindness is added to the patient's natural dread of the disease, the condition is indeed terrifying.

Tuberculosis, focal infection, syphilis, and other infections often involve the eye, but the ocular lesion of such infections is relatively limited as compared with that of leprosy, even if we accept the lowest statistics as given by the various authorities. The statistics of the percentage of eye involvement vary greatly in the reports of various leprologists. This variation is easily understood in view of the following conditions: (1) Variation of the forms of leprosy in different localities, the benign forms being prevalent in some places and the malignant in others; (2) difference of opinion as to what constitutes an ocular complication for statistical purposes, a mere conjunctival hyperemia being sufficient for one investigation while only well-defined, typical lesions are included by another; (3) available diagnostic procedures, an examination by an ophthalmologist with a slitlamp would reveal a much higher percentage of involvement than an observation by a general physician with a loupe; and (4) duration of the disease, it being obvious that the ocular involvement would be higher in the advanced cases.

In addition to these factors, there has always been difficulty in reconciling the data of various investigations because of a lack of a clear classification of the various types of leprosy. Different criteria have been used, and numerous classifications have been advanced, but none has proved entirely satisfactory. For years the *Bacillus leprae* (Hansen) has been accepted as the etiologic agent of leprosy, but the classification continues to be clinical and topographical. As late as 1931, at the Congress of Manila, the lesions were spoken of as a cutaneous type, which was very malignant with many bacilli, and a nervous type, which was relatively benign. Even at that time there was another well-recognized separate form, the tuberculoid type, that could not be placed in the foregoing classification. The Congress of Cairo (March, 1938) made an attempt to remedy this by accepting two primary types—the lepromatous and the nervous, with the tuberculoid as a subdivision of the latter. Although this classification is based on criteria partially histopathologic, in many ways it does not clearly define the nervous type.

Recently a number of South American leprologists set up a new classification in which there are three fundamental types: the lepromatous, the tuberculoid, and a third intermediate form called the non-characteristic for lack of a better name. The tuberculoid type is benign, with very few organisms, whose prognosis is generally good inasmuch as many lesions tend to regress spontaneously. The lepromatous type is malignant, with many bacilli, and tends to involve the entire system including the eyes. The non-characteristic form tends to evolve toward one or the other of the two former types;

* A condensation of the report presented at the Pan-American Congress of Ophthalmology in Cleveland, 1941. The original paper was illustrated with 51 figures.

† Ophthalmologist of the Sanatorium "Padre Bento" of the Leprosy Prevention Service of the State of São Paulo, Brazil.

possibly being a type that will disappear when its characteristic features become better known. This classification is fundamentally histopathologic. It is difficult to use, but with experience may be applied to the great majority of cases. In doubtful instances, laboratory procedures will probably be sufficient to establish the exact diagnosis. With the use of this classification many inconsistencies disappear, particularly in the matter of prognosis and as to probabilities of ocular involvement.

I have had the opportunity to collect a series of 1,279 cases of leprosy classified on this basis. All of these cases have been under my own careful observation and have been examined with the slitlamp at least once a year, many of them oftener if the lesion were mild or progressive. This series tends to show not only the value of this classification but it also gives some definite figures as to the involvement of the various ocular tissues in the different types. Before the results of this study are given, a discussion of the common ocular lesions of leprosy should be presented to aid in a better and more complete understanding of these cases.

OCULAR LESIONS OF LEPROSY

EXTRAOCULAR INVOLVEMENT. The involvement of the skin of the brow and cheeks is very common in leprosy. The spread of these lesions into the eyelids is important to the ophthalmologists, for the lesions form an abundant source of organisms for direct invasion of the eye.

The lepromatous lesions have a predilection for the ciliary margin, more often than for the upper lid. They may be small and delimited or form large masses involving the entire ciliary portion of the lid. The tuberculoid lesions are common in the ocular region, often extending into the eyelids. This type of lesion, which is locally benign, may cause fixation of the

lids, at times, with some ectropion; it is the only effect on the eye of the tuberculoid type of leprosy that I have noted in this series of cases. Although rare, these cases show that contrary to the opinions of some authors this lesion has an effect on the globe, even though secondary. Of ophthalmic interest also is the erysipeloid reaction, in which there is a diffuse involvement of the lids resembling erysipelas. It is not important in that its course is benign.

Besides being a rich source of bacilli, the lid lesions are important in that they often affect the eye through the formation of a severe lagophthalmos. It is inevitable that in the healing of the lid lesions scarring would result, so that many of these lesions would result in a residual cicatricial lagophthalmos. In addition, a patient may show a paralytic type of lagophthalmos in which there is a peripheral lesion in the facial nerve, generally affecting the superior branch of the orbicularis. This may be found even in those cases wherein there are no local skin lesions. I have found that these facial-paralysis cases are quite infrequent, being especially found in hospitalized patients who have the terminal forms of leprosy. This infrequency is in contrast to the figures usually quoted in the literature, in which the incidence of facial paralysis is often over 50 percent. Many patients show a mixed type of lagophthalmos in which both the cicatricial and paralytic elements are present.

CONJUNCTIVA. The statement is usually made both in textbooks and in the literature that the conjunctiva is frequently attacked in leprosy. I believe that actual conjunctival involvement is very rare and that the commonly held idea is due to an error of interpretation.

A nodular infiltration of the tarsus and palpebral conjunctiva has often been described as occurring frequently, but such a lesion was not noted in my series. When

seen, they are probably due to secondary invasion from the lids or from the deeper tissues. In two of my cases no leprosy lesions could be noted in the lids clinically, but after intravenous administration of methylene blue, stained areas were noted in the tissues. Bacilli were proved to be present in these areas.

Isolated lesions in the bulbar conjunctiva have also been described as of frequent occurrence, particularly around the limbus. I think that such lesions in reality originate in the episclera and involve the conjunctiva secondarily. I have never seen a lesion of the bulbar conjunctiva that was confirmed by histologic examination.

There is no evidence that there is any such entity as a leprosy conjunctivitis. However, acid-fast bacilli are often found in the conjunctival cul-de-sacs in the absence of any lesion in the lids and with a negative nasal mucous membrane. In biopsy specimens from the bulbar conjunctiva in clinically normal cases, no bacillic lesions were seen deep in the stroma, even around the nerve trunks.

Invasion of pterygia by leprosy has also been frequently noted in the literature. Many pterygia were removed in this series of cases, but in none was there any histologic evidence of involvement with leprosy.

EPISCLERA AND SCLERA. Because of its extremely rich blood supply and looseness of tissue, the episclera presents an ideal site for the localization of leprosy lesions. These are of two general types: diffuse episcleritis and a localized or nodular episcleritis or scleritis.

The diffuse type is generally an acute process, presenting itself as a diffuse purplish discoloration typical of lesions situated below the conjunctiva. It is usually quite extensive, but generally of a very transient nature. This is so characteristic that I was never able to make a histologic examination.

The localized type at times occurs very suddenly as an acute nodule, sometime quite slowly as a true chronic lesion. It is usually near the limbus, but may occur well out in the bulbar conjunctiva. It is very often symmetrically placed in the two eyes. It almost always originally arises in the temporal portion. Although occasionally seen superiorly and inferiorly, I have never seen it arise nasally.

In the chronic cases it is first noted as a small, slightly elevated gelatinous nodule, dirty-yellow in color. As it causes no discomfort, it may remain unnoticed by the patient for years. It may then assume an acute character and within a few days become quite large. In other cases the course from the first is acute. In two or three days a large nodule may form from an apparently normal conjunctiva. These cases are almost constantly limbal in nature. There is usually some indefinite ocular discomfort in the acute type.

The episcleral lesion usually progresses toward the limbus, around which it may then tend to grow, giving an appearance suggestive of the limbal hypertrophy of vernal catarrh. However, I have never seen it completely surround the limbus. Once having reached that point, the lesion is progressive, with invasion of the cornea, which will be discussed later.

Bacilli are always found abundantly in these lesions. The ultimate histologic evolution is in the direction of a localized sclero-corneal leproma. This supports the conclusion that this lesion is a specific infiltration, probably metastatic.

CORNEA. The incidence of keratitis in leprosy is extremely high, primary involvement having been seen by me exclusively in the lepromatous type. Both eyes are usually affected; there is seldom an advanced lesion in one eye with the fellow relatively free. In time there is a more or less perfect similarity between the two corneas.

In primary leprous involvement of the corneas there are two types, an interstitial or infiltrative keratitis and a nodular keratitis or corneal leproma. These two types have, in general, a similar histologic background, since both of them usually arise by invasion of the cornea from episcleral lesions. They differ chiefly in clinical characteristics, the former being diffuse, the opacity extending in time throughout almost the whole extent of the cornea, with little change in thickness or luster. The latter consists of a localized module with an enormous, up to tenfold, thickening of the cornea. Both types are

first noted in the superior temporal quadrant (fig. 1), starting as a number of small white dots in the anterior third of the corneal stroma which coalesce to form a small area of deep infiltration (fig. 2).

Fig. 2 (Mendonça de Barros). Corneal infiltration under high magnification (Oc. orthosk. 12.5, Obj. 6, lens of 7 cms. focus). A number of small nodules which serve as the center of a delicate zone of infiltration. There is a true punctate indentation of the cornea.

This extends nasally and inferiorly so that the inferior nasal quadrant almost always retains its transparency the longest. In only one case was involvement of the inferior nasal quadrant originally noted.

In all cases the infiltration was chiefly in the central third of the stroma. In most instances there were areas of denser infiltration resembling tiny scattered nodules scattered throughout the opacity. In some cases the infiltration remained uniform, extending throughout the whole thickness of cornea. Again, the nodules were quite superficial, causing a surface elevation. In a few cases, the infiltration was both superficial and very deep, leaving the intermediate layer almost uninvolved.

The extraordinary predilection which the infiltrative foci have for the corneal nerves is extremely interesting (fig. 3). These nerves are usually easy to see, often showing not only well-defined nodular formations attached like beads, but also a diffuse, surrounding infiltration. Eventually fusion of the foci occurs.

Fig. 1 (Mendonça de Barros). Infiltrative keratitis ("Sclerotic scatter." Microscope with Oc-2, Obj. 2—5.5 by 2X, right eye). The infiltration is most marked in the superior temporal quadrant, and consists of numerous rounded and well-defined foci, which occupy the anterior layers of the stroma. No vessels are seen. This case is shown by direct slit-illumination in figure 2. This type is called "superficial punctate keratitis of leprosy."

surprisingly symptom free. There is usually no ciliary infection, pain, or photophobia, and the visual acuity remains good for a comparatively long period.

In a manner surprisingly uniform, infiltrative keratitis practically always was

Vascularization is not an early finding and is usually present only late in the course of a keratitis. The vessels appear only after the keratitis has attained a large size. The vessels are usually both superficial and deep. Erosions are rare in this form of keratitis and are usually associated with an edema of the epithelium.

The course of this type of keratitis is practically always progressive, the infil-

appears in those patients who are victims of a massive infection in contrast to the infiltrative form, which is often seen in patients with a minimal infection.

As a rule leproma of the cornea represents invasion of the cornea from an episcleral lesion which is usually seen near the temporal limbus. In the region of the episcleritis there is first noted a slightly yellowish infiltration of the deep stroma with early vascularization. Usually, this lesion slowly develops into a localized nodule, but the nodule formation may take place very rapidly. Occasionally the nodule may form from the diffuse infiltrative type of keratitis by coalescence of the small infiltrates. These nodules have a typical dirty-yellow color resulting from a large number of Virchow cells full of fat. These lepromata are generally bilateral and often symmetrical. The vascularization is usually very marked. The lesion is frequently so indolent that it is practically symptomless except for the irritation that may arise from its size. It is very hard and often undergoes central necrosis. As the nodule spreads throughout the cornea, the progressive necrosis causes a weakening of the corneal stroma with a resulting staphyloma and eventual loss of the globe.

Besides these two forms of primary corneal involvement, there are a number of cases of keratitis which are secondary to other lesions. A small number of cases of ulcerative keratitis were found present in both cicatricial and paralytic lagophthalmos. This is about the only type of leprotic keratitis in which there is true corneal ulceration. Keratitis secondary to iridocyclitis is due to the toxic action of the massive anterior-chamber exudates. These coming in contact with the posterior surface of the cornea cause an invasion of the corneal stroma with vascularization, which often tends to be ring-shaped near the limbus. Rarely are cases of bulbous

Fig. 3 (Mendonça de Barros). Perineural infiltration of the cornea (patient Atilio C., mic. with Oc. 4, Obj. 2, employing the direct method and focusing upon the center of the nerve bundle toward the periphery of the cornea). Note the sleeve-like formation around the nerve as well as several well-defined nodules.

tration eventually spreading throughout the entire extent of the cornea. In only a few cases did this infiltration localize in the upper temporal quadrant, become vascularized, and remain unchanged for years. Usually a diffuse leucoma develops with flattening and shrinking of the cornea. There is usually no clearing of the corneal opacity although in a few cases this has occurred. In my opinion it is due to a hyalinization of corneal scar.

I have presented previously a series of 62 cases showing that in the great majority of the cases bacilli were present. The localization of the infiltration in the anterior third is probably due to the fact that the spread is from the episclera and along the corneal nerves.

Nodular keratitis differs from the previous form by the development of a discrete inflammatory mass. This lesion often

keratitis seen in cases of long-standing keratitis with degeneration.

IRIS. Although less frequently attacked than the cornea, iris involvement is very common. However, I have never seen any case in which the iris lesion was noted without previous involvement of the cornea. The cases of iritis as seen by me may be divided into a diffuse lesion with acute and chronic forms and the miliary lesion in nodular iritis.

Acute diffuse iritis of leprosy presents little or nothing typical of the disease. It is usually an acute exacerbation of a pre-existing chronic iritis, and after one or more acute attacks reverts to a chronic type. The onset is usually abrupt, with intense pain and photophobia, blurring of vision, and blepharospasm. Although binocular involvement is almost the rule, the acute attack is not usually simultaneous. The attack often follows cauterization of a limbal episcleral nodule. On examination, ciliary infection is not commonly observed, but corneal edema, keratic precipitates, and anterior-chamber exudates are the rule. These gelatinous masses are usually composed of fiberlike filaments which branch, often forming a diffuse web, and tend to develop on the anterior surface of the iris. The attack is of variable duration, but is usually in direct relation to the general condition of the patient. In favorable cases the symptoms may disappear in two to three weeks, but many cases become chronic. Frequent recurrences are very common. It is worth noting that this is the only acute form of ocular leprosy. A peculiarity often noted is a resistance to dilation with atropine.

In the chronic type there is almost complete absence of inflammatory symptoms, the only complaint being slight blurring of vision. There are usually some corneal edema, faint aqueous flare, fine deposits in the endothelium. Often exudates in the anterior chamber, such as are observed in

the acute form, are seen. Also, as in the acute form, eventual bilateral involvement is the rule.

As in any iritis, both the acute and chronic forms show eventual posterior synechiae, iris atrophy, and organization of the anterior-chamber exudates. As noted previously, these exudates often form a ring-shaped band at the base of the iris with secondary keratitis. If marked, this type also commonly is associated with secondary glaucoma.

The miliary or nodular type of iritis is characterized by the presence in the iris stroma of small translucent nodules seen only with the aid of the slitlamp (figs. 4 and 5). Very often any other inflammatory sign is completely absent and the vision normal. This reaction may be present for years without great damage to the eye. The nodules are most often seen in the region of the sphincter, where they may form a complete collar. They may disappear to be replaced by a new formation of nodules. There may be coalescence of some few nodules, but a very large conglomerate nodule is never seen. A pseudo nodule may appear after the diffuse form. This consists of a tiny bit of the commonly seen anterior-chamber exudate. It is noted that these are situated on the surface of, and not in, the stroma.

AFFECTION OF THE POSTERIOR SEGMENT. Although there is no satisfactory explanation for it, leprologists, almost unanimously agree that the posterior segment of the eye is spared almost without exception. Personally I have never seen a case of proved posterior-segment involvement.

RESULTS OF OBSERVATIONS

As stated previously, I have personally observed 1,279 cases of leprosy, each being carefully examined with the slitlamp at least once a year, oftener if the case is early or progressive. The high percentage

of involvement observed by me is due to the slitlamp examination, for without it this incidence would probably be no higher than 30 to 40 percent. At the time of the last examinations, the 1,279 patients were

of the episclera alone is difficult to diagnose, owing to its small size and the fact that it is deeply placed. This small percentage does not invalidate my contention that the episcleral involvement usually

Fig. 4 (Mendonça de Barros). Miliary nodules in the iris (right eye, patient P. G., Oc. 2, Obj. 2, diffuse illumination). Myriads of miliary nodules are found in the iris, especially temporally, filling the crypts; others are seen in the depths of the mesodermal layer. The pupil is round. There is no exudation into the aqueous humor.

Fig. 5 (Mendonça de Barros). Nodular cauliflower formations (Oc. 12.5, Obj. 6, diffuse illumination, left eye). There are sharply rounded deposits on the cornea; marked atrophy of the iris tissue. In this case, the formations were observed after intense exacerbations of acute diffuse iritis.

classified from their systemic findings as follows:

Type	No. of Cases	Percentage
Lepromatous	826	64.7
Tuberculoid	261	20.4
Noncharacteristic	190	14.9

In the lepromatous type there was ocular involvement in 540 cases of the 826 or about 65.3 percent. In each of these 540 cases there was involvement of the cornea; in other words, no case in which the eye was involved was without corneal lesion. Clinically, I could verify the presence of an episcleral lesion in only 8.5 percent of those with ocular disease, or only 5.6 percent of the lepromatous group. This number is small, for the early involvement

precedes the corneal lesion, for many of these episcleral nodules are almost microscopic. The iris was attacked in 180 cases—24.5 percent of the lepromatous group and 35.1 percent of those with ocular involvement. Of these, 139 were of the diffuse type, acute or subacute. Miliary nodules were noted in 69 patients. In 33 cases the routine examination showed signs of an old, healed iritis. Of these, 16 patients had a subsequent acute attack.

In the tuberculoid type there were only 4 cases of ocular disease in the total number of 261. In two of these cases there were lesions of the buccal region, and first a paralytic, later a cicatricial lagophthalmos with exposure keratitis. The third was a case of typical facial paralysis with

marked ectropion and lagophthalmos. The fourth case presented an extensive facial lesion, with resultant ectropion and involvement of lid margin of the opposite side. Thus in these cases there was no direct ocular involvement.

Noncharacteristic leprosy was present in a total of 196 patients, a great majority of whom were children. In 19, or about 10 percent, the examination was positive, all of them showing corneal lesions. In 17 cases the findings were doubtful. In the positive cases, the ocular lesions suggested that the leprosy was of the malignant form, even though the general type was noncharacteristic. The course of these cases will be carefully observed to determine whether the ophthalmic examination is of value prognostically in the nonchar-

acteristic type of leprosy.

In conclusion it can be stressed that the ocular complications of leprosy are restricted to the anterior segment, the cornea being usually involved. Iritis is also common, but found only in conjunction with corneal disease. The keratitis is thought to be due to extension from limbal episcleral lesions. The primary ocular lesions are practically limited to the lepromatous or malignant type of general disease in which many bacilli are present. The ocular lesions are only secondary to facial involvement in the benign tuberculoid form. In the noncharacteristic form, common in children, the ocular findings may be of prognostic significance.

Rua Marconi, 34-4º.

DISCUSSION

DR. PETER C. KRONFELD (Chicago): Dr. Mendonça de Barros is no stranger to the United States of America. He is the author of the monograph "Some clinical aspects of the ocular involvement in lepers," which was published under the auspices of the Department for the Prophylaxis of Leprosy of the State of Brazil one year ago. This monograph, though written in the Portuguese language, also contains a slightly condensed translation into English which together with the excellent illustrations has put the author and the sanatorium "Padre Bento," where all the work was done, on the map for the North American readers. Today Dr. Mendonça de Barros has probably presented here as vivid and comprehensive a picture of leprosy of the anterior segment of the eye as has ever been presented at an ophthalmologic meeting. Having been asked to open the discussion, I believe it would be a mistake if I tried to add to this picture by reporting some of my personal experiences

with regard to ocular leprosy. It is true that I have had the opportunity to examine a large number of patients with ocular leprosy. These were inmates of various leprosaria in the Far East, in China, in Japan, and in the Philippines. In most instances, however, I saw these patients only once and had only a loupe and a flashlight at my disposal. At the Peking Union Medical College, with which I was associated from 1933 till 1939, I saw only very few lepers, who usually were admitted for the treatment of conditions other than their leprosy. The ocular manifestations of leprosy which I saw in these patients were, in general, on the same order as those shown and discussed here today by Dr. Mendonça.

I believe that as the first discussant it is my duty to recognize the special opportunity constituted in Dr. Mendonça's presence here. And I hope he will not mind my asking him questions pertaining to problems of leprosy which have not been mentioned in his paper. Physicians prac-

ting in the Far East are placing considerable stock in the so-called climatic theory, which was lately expressed again in a study by Shionuma Einosuke (Lepro, Osaka, 1939, v. 8, p. 57). According to this author the severity of the ocular symptoms depends to some extent upon the climate. The higher the temperature the milder are the ocular symptoms and vice versa. In general, leprosy is supposed to be a milder disease in the tropics than in a moderate climate. The Japanese author has recommended to the government that leprosaria should be located only in the southern parts of Japan. Viallefont and Fuentes have expressed a similar view (Ann. d'Ocul., 1939, v. 175, p. 380). I would like to get Dr. Mendonça's opinion with regard to this question.

We have been following with a great deal of interest the controversy that has been going on in the Brazilian ophthalmologic literature with regard to the question of early choroidal involvement in leprosy. The viewpoint of the pathologist

who sees more late than early stages of the disease (Ginsberg in Henke-Lubarsch's "Special pathology") is that the retroequatorial portion of the uvea is usually spared. Most clinicians have agreed with this view. It was therefore surprising when Hoffman reported early clinical choroidal involvement. The recent paper by Sergio Valle (Arqu. braz. Oft. 1938, v. 1, p. 31) seems to take a very sensible stand in the matter. Valle admits that the course and the manifestations of leprosy may vary in different countries. He observed choroiditis in a number of lepers, which, he believes, was probably caused by tuberculosis or lues. He summarizes that the leprous etiology of choroiditis has not been proved anatomically or clinically.

While a very remote subject for most North American ophthalmologists, this discussion of a disease that affects in considerable number in a neighboring country I am sure has been of great interest and value.

CONCENTRATION OF PENICILLIN IN THE AQUEOUS HUMOR FOLLOWING SYSTEMIC ADMINISTRATION*

ARNO E. TOWN, LT. COMDR. (MC), U.S.N.R., AND MARGARET E. HUNT,
PHM1c, U.S.N.R.
New York

Penicillin has been used for infections of the eye with varying degrees of success. Some types of infection, such as gonorrheal ophthalmia, have been shown to respond readily to this therapeutic agent whereas the intraocular infections respond with difficulty, if at all. To determine what might be expected from systemic therapy an investigation of the concentration of penicillin in the aqueous humor in relation to blood levels was undertaken.

Von Sallmann and Meyer¹ had previously shown that local application, with iontophoresis, as well as intravenous injection of penicillin resulted in a demonstrable concentration of the agent in the aqueous humor. A careful study by Struble and Bellows² revealed the distribution of the agent in various structures of the eye following parenteral and topical application.

No reference to the effect of varying systemic dosages on concentration of penicillin in the eye was found. In a report on the clinical efficacy of the drug in ophthalmic diseases, Keyes³ indicates that little is known about the secretion of penicillin into the secondary aqueous in the presence of a high blood concentration. He also points out that the rapidity with which the level of penicillin in the aqueous is reduced by normal drainage has not been ascertained.

The opinions and views set forth in this article are those of the writers and are not to be considered as reflecting the policies of the Navy Department. A thesis presented to the American Ophthalmological Society in partial fulfillment of the requirement for membership.

EXPERIMENTAL PROCEDURE AND RESULTS

Rabbits were chosen as the experimental animal, subsequently monkeys for a series of confirmatory experiments. Commercial preparations of the sodium and calcium salts of penicillin were administered by the intravenous or intramuscular route.

The concentration of penicillin in blood serum was determined for correlation with that found in the aqueous humor. For this, samples of blood were withdrawn by cardiac puncture or from an artery in the ear at intervals of 5, or, in some instances, 10 minutes prior to collection of aqueous humor.

Employing a fine hypodermic needle and a syringe, paracentesis of the cornea was performed for withdrawal of approximately 0.2 ml. of aqueous humor. Secondary or plasmoid aqueous was collected 40 minutes after withdrawal of the primary fluid, at which time it had re-formed in sufficient quantity to bring the tension in the anterior chamber to normal.

The Rammelkamp⁴ method of assay was employed. This is a serial-dilution method, using the hemolytic streptococcus as test organism. Relative Oxford units are calculated by comparison with an assay done concurrently on a standard solution. Under conditions of the test, a concentration of 0.0195 units of penicillin per milliliter of the test solution was required for complete inhibition of the organism.

The animals were tested in experimental groups of four or five. In the early studies one animal in each group

served as a control, receiving no penicillin. At no time was an inhibitory effect demonstrated with the blood serum or aqueous humor of these control animals against the streptococcus used in the penicillin assay.

Individual animals showed a marked variation in the concentration of penicillin found in the blood and aqueous humor following intravenous injection. In a total of 16 rabbits, weighing between 2.4 and 3.4 kilograms, four served as controls and

approached or equaled that in the blood serum collected 10 minutes earlier, and the values for the 12 animals were from 0.0781 to 2.5 units per milliliter of fluid.

Following intramuscular injection there was found to be less variation for the individual animals than after intravenous injection. The concentration of penicillin found in the blood serum and aqueous humor of 35 rabbits receiving the therapeutic agent by intramuscular route in varying dosage is shown in figures 1 and

Fig. 1 (Town and Hunt). Penicillin levels in blood of rabbits following intramuscular injection.

each of the remaining 12 received 30,000 units of penicillin. Blood samples withdrawn at 25 minutes from these 12 test animals yielded from 0.625 to 10 units per milliliter of serum and samples at 60 minutes varied from 0.0781 to 2.5 units per milliliter of serum. Concentrations of 0.0195 to 0.1563 units per milliliter were found in the primary aqueous humor withdrawn at 30 minutes. In each instance the concentration in the secondary aqueous humor withdrawn 70 minutes after the intravenous injection of penicillin

2. In the serial-dilution method of assay used, the result is based on the highest dilution giving complete inhibition of the test organism. Since each successive dilution results in a concentration one half that of the preceding sample, the true endpoint of inhibition lies in the range between the dilution giving complete inhibition and the next higher one. In these figures, that range is indicated by a bar at each point on the abscissa. Penicillin was found in demonstrable quantity in each sample tested.

The concentration of penicillin in the blood of the 35 animals receiving intramuscular injection, was found to increase as the dosage level was raised (fig. 1). The curve of blood concentration rises gradually as the dose is increased to 5,000 units per kilogram of body weight. At that point the curve levels off until a dosage of 9,000 units per kilogram is reached, when it again climbs sharply. It may be that the ability of the kidney to excrete penicillin is not exceeded by this

ing dosage, the rise in concentration in the aqueous was proportional, but a high level was never obtained. The concentration was, however, sufficient to be considered of therapeutic value with all doses above 7,000 units per kilogram of body weight. Following paracentesis, the aqueous fluid re-formed within 40 minutes with a concentration of penicillin which approached or equaled that of the blood serum. It is well known that this secondary aqueous humor contains many

Fig. 2 (Town and Hunt). Penicillin levels of aqueous humor of rabbits following intramuscular injection.

intermediate dosage of 5,000 to 9,000 units per kilogram of body weight. Larger dosage may then result in a sharp rise of blood concentration, when the absorption rate exceeds the excretory rate.

The primary and secondary aqueous humor of these same 35 animals was withdrawn following the collection of blood samples to determine the corresponding penicillin concentration in the aqueous at the varying dosage levels (fig. 2). In the primary aqueous humor of animals receiving small doses, the penicillin levels were found to be low. With increas-

ing dosage, the rise in concentration in the aqueous was proportional, but a high level was never obtained. The concentration was, however, sufficient to be considered of therapeutic value with all doses above 7,000 units per kilogram of body weight. Following paracentesis, the aqueous fluid re-formed within 40 minutes with a concentration of penicillin which approached or equaled that of the blood serum. It is well known that this secondary aqueous humor contains many

The rate of loss of penicillin from the blood and aqueous humor of rabbits was studied following intravenous and intramuscular injections. Blood levels fell rapidly after injection by the intravenous route, as is indicated by the finding that 80 minutes after injection of 30,000 units in a rabbit weighing 2.8 kilograms, penicillin was present in a concentration of only 0.0391 units per milliliter of serum. In the primary aqueous fluid the level

muscular injection. Following paracentesis in the presence of a high blood level, the concentration in the aqueous rose sharply. Experimental results showed that the rate of decrease of penicillin in this secondary aqueous followed, in general, the curve of decrease in the blood. Although the concentration did not reach the high levels found in early blood samples, it was resorbed more slowly.

In one group of rabbits each animal,

Fig. 3 (Town and Hunt). Penicillin levels in aqueous humor and blood of rabbits following intramuscular injection of 30,000 units.

reached a slight elevation at 45 minutes, after which time it descended in a definite but gradual curve.

With intramuscular injection the decrease of concentration in the blood was somewhat more gradual than with intravenous injection, although it was still rapid, as will be seen in figure 3. The peak of concentration in primary aqueous fluid occurred at 50 minutes following injection by this route. Although the level was never high, it would appear to be of therapeutic significance that this low level was maintained fairly constantly for over 90 minutes following a single intra-

weighing approximately two kilograms, received 15,000 units every three hours over a period of 24 hours. Assays of blood serum and aqueous humor showed no cumulative increase in concentration of the penicillin.

Results obtained with monkeys were comparable in all instances to those obtained with rabbits. The relative concentration of penicillin in the blood serum and aqueous humor was similar and all findings confirmed those in the rabbit.

CONCLUSIONS

The foregoing findings show that, fol-

Following systemic administration, penicillin is present in the aqueous humor in concentrations that are low in relation to blood levels. Massive doses of the therapeutic agent are required for an appreciable increase in this level. Penetration into the aqueous humor appears to occur slowly, and the decrease in concentration

is gradual. Continued, frequent injections maintain a low level without increment. Following paracentesis the aqueous humor is re-formed within 40 minutes with a concentration of penicillin approximating that of the blood serum.

FASCIA-LATA TRANSPLANT FOR RETROTARSAL ATROPHY OF UPPER LID FOLLOWING ENUCLEATION

NORMAN L. CUTLER, LT. COL. (MC), A.U.S.
Menlo Park, California

About 30 percent of all patients who have had an enucleation develop a sinking of the orbital contents posterior to the septum orbitale in the upper lid. Attempts have been made by artificial eye makers to overcome this condition by enlarging the upper part of the prosthesis with a bulge to press the upper-lid fold

ward on the levator and interfere with the action of this muscle. Since it is really the restoration of the normal lid fold that is desired and not the filling-in of the orbital contents, it was decided to place fascia between the septum and the orbicularis. If the lid fold on the normal side is examined, it will be observed that it is only necessary to add bulk and weight in the lid immediately below the brow line to restore this fold. In this region the greatest space is available between the skin of the lid and the septum orbitale (fig. 1) and also between the orbicularis and the levator. If the fascia is placed lower than this, pressure is exerted on the levator and a partial ptosis results. One further precaution is necessary. The fascia must be placed beneath the orbicularis, otherwise it will adhere to the skin, and the result is induration and scar-tissue formation.

Up to the present time 134 patients have been operated upon by various members of the staff at this hospital.

Fig. 1 (Cutler). Dissection and scheme to show insertion of fascia lata.

forward. The results have not been too gratifying since this procedure limits the movement of the prosthesis.

According to Spaeth¹ fascia and fat and scales of cartilage have been used to fill in this defect. Plastic material has also been used.² The recent literature discloses no satisfactory study of this problem.

Any material placed behind the septum orbitale has a tendency to disappear into the orbit and may exert pressure down-

OPERATIVE PROCEDURE

Anesthesia. Three different methods of anesthesia were tried: General (either inhalation or pentothal sodium); combination of spinal and local; and local. The last-named method was found to be the most satisfactory.

Obtaining the fascia. Only fresh fascia lata obtained from the patient himself has been used up to this time. This is procured from the lateral aspect of the thigh. Any standard procedure may be used.

The lateral aspect of the thigh down to the fascia lata over an area measuring 12 by 30 cm., beginning about 5 cm.

below the trochanter is infiltrated with 1-percent procaine containing 1:50,000 adrenalin. A skin incision about 5 cm. long is made lengthwise, beginning about 5 cm. below the trochanter. This is carried down through fat to the fascia. The latter is exposed for the length of the incision. Parallel incisions are then made lengthwise through the fascia 10 to 12 mm. apart; the upper end is cut across and carried through a Masson stripper, and while this end is held with a clamp, the stripper is passed down the leg to the desired length (about 15 cm.) and the fascia cut by rotating the handle of the stripper. The fascia is then removed. Difficulty may be encountered with transverse fibers near the upper end of the fascia; these can be cut with a needle guide which has the notch sharpened. The incision is closed with 00 chromic catgut sutures and interrupted silk sutures for the skin. No disfiguring scar remains.

This fascia is then placed in normal saline until the lid has been made ready

Fig. 2 (Cutler). Two loops of medium black silk are drawn through the tunnel in the lid.

Fig. 3 (Cutler). Fascia being drawn into position.

to receive it, as described below.

Lid operation. The upper lid below the brow line is infiltrated with 2-percent novocaine and 1:50,000 adrenalin over an area extending from the nose to 2 cm. beyond the outer canthus. This procedure is advisable even if general anesthesia is used, as it facilitates dissection. A skin incision about 1.5 cm. long is made just lateral to the outer canthus and parallel to the curve of the brow. This is carried through the orbicularis. With curved scissors (Stevens or similar scissors), sharp and blunt dissection is used to tunnel under the orbicularis toward the nose, care being taken to follow the curve of the brow (fig. 1). Two loops of medium silk are now carried through the incision from the temporal side with an aneurysm needle. The loops protrude through the temporal incision (fig. 2).

Previously obtained fascia is then prepared and placed in the following manner: A double strip of fascia is laid along the curve of the lid and cut to the desired length. Two double strips of fascia are thus obtained. Each piece of fascia is then held in a mosquito clamp at the middle (fig. 3) and shredded with a sharp-pointed Bard-Parker knife. The fascia is smoothed flat and each strip laid

Fig. 4 (Cutler). A, fascia in position ready for tapering of ends. B, final closure.

through a separate loop of the previously placed sutures (figs. 3 and 4) and then drawn into the lid. The fascia should project a little through each incision. The sutures are cut and removed and the looped ends of the fascia cut. The protruding ends of the fascia are tapered with scissors and tucked under the orbicularis. The latter is then closed with one or two 4-0 chromic catgut sutures, and the skin is closed with one or two 4-0 silk sutures (fig. 4). The fascia is then massaged slightly to make sure that it is lying flat, and a Wheeler patch is applied. The prosthesis may be left in the socket if desired.

Postoperative course. The dressing is removed in three or four days and the skin sutures removed. If unusual lid edema is noted, a dressing may be reapplied for an additional two days. Some edema persists for a week to 10 days. In occasional cases, some edema may persist for several weeks. If, after all edema has disappeared, it is found that insufficient fascia has been implanted, an additional amount may be placed where it is

needed. If too much has been used, some of the strands can be readily removed.

Patients have been observed for periods up to four months. One patient was killed in an automobile accident approximately $3\frac{1}{2}$ months after the implantation. At autopsy the fascia was found to be unchanged in its original position (fig. 5). There was still some round-cell infiltration present. This patient had a somewhat prolonged edema of the lid postoperatively which gradually receded. The pre- and postoperative photographs are shown in figures 6 and 7. Following is the report of the pathologist:

"Sections through the fascia-lata implant in the left upper eyelid show viable fascia. There is no necrosis. There are, however, foci of granulomatous inflammation, characterized by exudation of lymphocytes, proliferation of histiocytes, and numerous foreign-body-type giant cells. There is also deposition of crystalline pigment, presumably hematogenous in origin. The fascia gives evidence of a foreign-body reaction."

Complications. The complications that may arise can, for the most part, be

Fig. 5 (Cutler). Drawing made at autopsy, $3\frac{1}{2}$ months after implantation of fascia.

Fig. 6 (Cutler). A, preoperative view of lid. B, two weeks' postoperative view of lid.

Fig. 7 (Cutler). A, preoperative view of patient in figure 5. B, 3 months' postoperative result.

guarded against. The fascia must be put in smoothly in order to insure a smooth appearance. It must be placed close to the brow line, and the lower side of the dissection must follow the curve of the brow. Otherwise, the fascia will take the shortest course across the lid and be too low.

Care must be taken to keep the fascia under the orbicularis to prevent scarring. One patient, for some reason, showed a

continued reaction and swelling for several weeks, and the fascia had to be removed.

SUMMARY

A procedure for restoring the normal upper-lid fold after enucleation, used on 134 patients, is described with a postmortem report on a patient operated on 3½ months earlier.

Dibble General Hospital.

NONPERFORATING CYCLODIATHERMY FOR THE TREATMENT OF GLAUCOMA*

FRANK C. LUTMAN, M.D.†

Rochester, New York

Vogt and his associates^{1, 2, 3}, have recently introduced the cyclodiathermy operation for the treatment of glaucoma. The operation employs a diathermy needle similar to that used for retinal separation to destroy a portion of the ciliary body by multiple punctures through the overlying sclera. An atrophy of the ciliary body has been confirmed histologically;^{1, 4} therefore a reduction in the formation of aqueous would be expected to follow. Vogt's procedure has been designated as "perforating cyclodiathermy" to distinguish it from the "nonperforating" method employed by Albaugh and Dunphy,⁴ who used contact with a broad electrode to the sclera over the ciliary region. The following report is based upon the observations made on 28 eyes afflicted with various types of glaucoma which were treated by nonperforating cyclodiathermy.

The operative procedure followed closely the originally described method.⁴ Subsequent to instillation of an anesthetic and a retrobulbar injection of procaine and adrenalin, a conjunctival flap was reflected toward the limbus over half the eyeball. The tip of a 2-mm. rounded electrode was used in the earlier operations, and later the flat end of a round stainless-steel pin 2 mm. in diameter. A small Bovie high frequency electro-surgical unit set at 35-40 furnished the coagulation current. The electrode was held in contact with the sclera from 4 to 5 seconds to form a single row of points over the

ciliary region. The amount of current, the time, and the degree of pressure upon the sclera are all variable and arbitrary. The optimum area of coagulation was for the 2 mm. covered by the tip of the electrode and extending for not more than 0.5 mm. beyond its edge. Coagulation exceeding this amount led to an excessive postoperative reaction. A closure with a tight running silk suture was found the most effective means of avoiding a postoperative retraction of the conjunctiva with an exposure of the treated portion of the sclera. In the few instances where retraction occurred, the sclera was slow in healing. Because of the possible danger of too extensive destruction to the anterior circulation of the eye, no more than two-thirds of the ciliary body was treated in any one eye. At first, because intraocular pressure was not immediately relieved by the operation, there was hesitation in employing atropine postoperatively. Later atropine was used routinely and in most instances was continued until the uveitis subsided. At the first dressing of the atropinized eyes, the pupils were dilated only in the segment not operated upon. These pupils remained permanently oval, and the iris failed to respond to light over the segment that had undergone operation.

Usually there was ocular pain for about 24 hours postoperatively, at which time the eyes were comfortable regardless of any abnormally high intraocular pressure. Albaugh and Dunphy⁴ attribute a postoperative rise in tension to a mechanical shrinking of the sclera with reduction of the total contents of the eyeball. Apart from this action there is the effect of the adrenalin used, for adrenalin temporarily

*From the Department of Surgery, The University of Rochester School of Medicine and Dentistry, and The Strong Memorial Hospital.

† Now Lt. (MC), A.U.S.

reduces intraocular pressure in a glaucomatous eye although it may later induce a stasis and edema.⁵ The elevated tension is probably due principally to the injurious effect of the diathermy upon the endothelium of those vessels of the ciliary body that are not actually destroyed. The injury is comparable to a burn upon the body surface where the transudate accumulates in cutaneous blebs. Occurring within the unyielding confines of the eyeball, this process is followed by extreme elevation of intraocular pressure. Occasionally, to counteract this, the operation was followed by a paracentesis sufficiently large to remain open for at least 24 hours.

In most instances intraocular pressure dropped slowly and steadily for several days before it returned to normal. There was a further reduction to a point of extreme hypotony, lasting for weeks or until the uveitis subsided, when the tension returned to normal or again became elevated. During the stage of hypotony the anterior chamber was reduced as much as a third of normal depth. Several eyes were tender during this period. The pre-operative incompenation and high tension were never reached by such eyes as returned to a glaucomatous state postoperatively. A most striking sequel of the operation was the relief from ocular pain.

A constant occurrence was a faint opacification with anesthesia of one half to two thirds of the corneal surface corresponding to the treated segment of the bulbs. When three fifths of the ciliary region was treated, as much as four fifths of the cornea became anesthetic. For several subsequent weeks this hazy and anesthetic portion of the cornea dried quickly upon exposure. Later the corneal smoothness was completely restored, although in a few cases there were permanent deep nebulous opacities. These, however, may have arisen from the glaucoma. Corneal anesthesia over the segment

where it was first observed remained complete and unchanged in all these cases except one, where slight sensitivity returned. Some cases were under observation for more than two years. A number of cyclodiathermies were done upon the upper part of the bulb so that the anesthetic portion of the cornea was protected by the upper lid. This position of the cyclodiathermy did not interfere with a subsequent cataract extraction through an enlarged superiorly located keratome incision under a conjunctival flap in case 19. In case 13, the cyclodiathermy was below, the cataract incision located above.

A uveitis with a cyclitis of variable severity and duration follows the necrosis of the ciliary body and overlying sclera. In this series there was a greatly increased aqueous ray which sometimes lasted for months. However, cells were infrequent in the anterior chamber. Some degree of posterior synechia usually occurred, and a mild iris atrophy was a frequent late finding. A thin membrane formed across the pupillary area of the aphakic eyes. Unless emptied by paracentesis, the anterior chamber usually remained at least partly formed, which is favorable in avoiding peripheral synechia.

Danger of a direct thermal injury to the lens at operation seems improbable. Following any of the usual operations for glaucoma, even when no apparent injury occurs to the lens, cataractous changes are prone to form. With the use of cyclodiathermy a sudden acute fall of intraocular pressure is avoided. A possible danger to the lens exists in its exposure to an extreme hypotony, an iridocyclitis, and to the degenerative products from the tissues destroyed by the diathermy current.

In spite of the destruction of a substantial part of the aqueous-forming structures, some eyes returned to an abnormally high tension when recovery from the operation had occurred and when the

TABLE 1
DATA ON 28 CASES OF GLAUCOMA TREATED WITH CYCLODIATHERMY

Case	Patient Age, Sex	Diagnosis and Previous Treatment	Vision and Tension before Cyclodiathermy	Cyclodiathermy	Results
1.	80 ♂	Eye blind for 7 yrs. Iris atrophic, vascularized.	No light perception; tension 55 mm. Hg	Lower 1/3	4 dys. postoperatively, tension 30 mm.; 3 wks., 21; 2 mos., 16.
2.	59 ♂	Bilateral old retinal separations. Left eye painful, irritated. Mild diabetes.	No light perception; tension 90 mm. Hg	Upper 2/5	1 month postoperatively, tension 35 mm. No pain. Patient died soon after this from uremia.
3.	76 ♀	Acute congestive glaucoma 10 wks. following extracapsular combined lens extraction. Miotics failed.	6/200 (previous to cataract removal); tension 90+ mm. Hg	Upper 3/5	Tension followed for 16 mos. never above 21 mm. Corrected vision 6/7.5-2; Field, white 3/1000 5 8 27
4.	67 ♀	Irritation and pain 10 wks. after right central venous thrombosis. Miotics failed.	Light perception; tension 90 mm. Hg	Upper 3/5	1 wk. postoperatively, tension 42 mm.; 2 wks., 30; 5 wks., 25; 6 wks., 35.
5.	80 ♀	Right eye painful and congested for 10 dys. following central venous thrombosis of unknown duration.	Light perception; tension 90 mm. Hg	Upper 1/2	2 dys. postoperatively, tension 47 mm.; 4 dys., 55; 4 wks., 65; 5 wks., 80. No pain. Light perception.
6.	60 ♂	Left extracapsular lens extraction.* iridencleisis* 4 yrs. previously. Eye painful, congested.	No light perception; tension 90+ mm. Hg	Lower 1/2 (lightly)	2 dys. postoperatively, tension 35 mm.; 3 dys., 23; 3 mos., 55. No pain.
7.	66 ♀	Intracapsular combined cataract extraction* 1 yr. previously. Compensated glaucoma. Miotics failed.	6/10; tension 56 mm. Hg	Upper 2/3	1 dy. postoperatively, tension 21 mm.; 21 mos., 21. Corrected vision 6/10-2; Field 15 40 15 38
8, 9.	52 ♀	In May, 1942, left acute congestive glaucoma for 33 dys.; right for 4 dys. "Rubeosis iridis." Severe vitreous hemorrhage. Moderate diabetic. Miotics failed.	R., 3/200, tension 90 mm. Hg; L. hand movements at 2 ft., tension 55 mm.	Lower 1/2 of each eye	3 dys. postoperatively, R. tension 40 mm., L. 55; 4 dys., R. 35, L. 40; 6 dys., R. 21, L. 25; 7 dys., R. 15, L. 17. Vision R. 7/200, L. 3/200. 30 mos. severe with atrophic changes.
10.	80 ♀	Intracapsular combined cataract extraction* 3 yrs. previously. Moderate bullous keratitis. Miotics failed.	No light perception; tension 40-65 mm. Hg	Lower 1/2	4 days. postoperatively, tension 21 mm. 6 mos., 21.
11.	68 ♂	Incompensated glaucoma 5 wks. after intracapsular combined cataract extraction. Miotics failed.	Light perception (previous to cataract operation); tension 40 mm. Hg	Lower 1/2	Moderately severe postoperative reaction; 1 yr. postoperatively tension 10 mm. Corrected vision 6/30.
12.	55 ♀	Bilateral chronic glaucoma untreated for 9 yrs. Right absolute glaucoma.	R. no light perception; tension 90 mm. Hg	Lower 2/5	Phthisis bulbi. 3 mos. postoperatively enucleated.
13.	75 ♂	Chronic uveitis. Iris congested. No posterior synechia. Immature cataract. Cycloplegics failed.	Hand movements; tension 60 mm. Hg	Lower 1/3	2 dys. postoperatively, tension 40 mm.; 7 wks., 21; 6 mos., 16; 18 mos., extracapsular combined lens extraction. Vision: hand movements.
14.	73 ♀	Acute congestive glaucoma. Trephining* failed.	Light perception, tension 90+ mm. Hg	Lower 1/2	4 mos. postoperatively, tactile tension normal. Light perception.
15.	59 ♀	Central venous thrombosis 1 yr. previously. A painful, congested eye with hyphemia.	No light perception.	Lower 3/5*	Lens changes and posterior synechia. For 1-1/2 yrs. postoperatively, hypotony and free of pain.
16.	69 ♂	Bilateral acute congestive glaucoma. Left basal iridectomy* 2 yrs. previously. Miotics failed.	6/60; L. tension 90+ mm. Hg	Lower 1/2	3 dys. postoperatively, tension 35 mm. 3 wks., 25; 6 wks., 35. For 16 mos., 16-20 under miotics. Vision 6/60; Field, white 7/1000 12 12 30 18
17.	37 ♀	Glaucoma 9 dys. after central venous thrombosis. Moderate incompensation. Blood pressure 226/130.	Finger counting; tension 55 mm. Hg	Upper 1/2*	10 dys. postoperatively, tension 20 mm. eyeball white in 2 mos.; 15 mos., tension 18.

20.	65 ♀	Extracapsular combined right cataract extraction* in 1936, and a later iridotomy* June, 1942. Pain and congestion. Fresh vitreous hemorrhage. Moderate diabetic.	Light perception; tension 30 mm. Hg	Upper 1/2	9 mos. postoperatively, tension 8 mm. No light perception.
21.	73 ♀	Bilateral chronic simple glaucoma. Right eye blind for 7 yrs. Moderate bullous keratitis. Slight congestion.	R. no light perception; tension 90+ mm. Hg	Upper 1/2	5 dys. postoperatively, 41 mm.; 10 dys., 25; 2 mos., 16; 1 yr., 10.
22.	68 ♀	Pain, congestion, iris vascularization, posterior synechia, 8 mos. after central venous thrombosis.	No light perception; tension 90+ mm. Hg	Upper 2/3*	For 2 yrs. postoperatively, comfortable, without pain. Phthisis bulbi.
23.	62 ♀	Intracapsular combined lens extraction* July, 1941. Sept., 1941, tension 40 mm. March, 1942, tension 46. Cyclodialysis,* miotics failed. Eye irritated for 11 mos.	Finger counting; tension 55 mm. Hg	Upper 1/2	2 dys. postoperatively tension. 11 mm.; 2 wks., 13; 2 mos., 29. Corrected vision 6/30. Comfortable.
24.	78 ♀	Bilateral acute congestive glaucoma superimposed upon chronic simple glaucoma. Miotics failed.	Hand movements; L. tension 80 mm. Hg	Upper 1/2 (Left)	1 wk. postoperatively, tension 19 mm.; 5 wks., 12; 2 mos., 48. Vision 6/200. Moderate cataractous changes and posterior synechia. Returned to miotics.
25.	65 ♀	Painful, congestive glaucoma 31 dys. following central venous thrombosis.	Light perception; tension 90 mm. Hg	Lower 1/2*	2 dys. postoperatively, tension 48 mm. Eye injected for 6 mos. Tension 20 or lower for 2½ yrs. Lens cataractous; posterior synechia. Comfortable without treatment.
26.	55 ♂	Internal strabismus, amblyopia exanopsia. Acute congestive glaucoma. Trephine, miotics failed.	Hand movements; tension 90+ mm. Hg	Lower 2/5	5 mos. postoperatively, hypotony. Phthisis bulbi.
27.	49 ♀	Bilateral chronic simple glaucoma. Trephining* failed. Right acute congestive glaucoma. Miotics failed.	Hand movements; tension 90+ mm. Hg	Lower 1/2	For 16 mos. postoperatively, tension 30–40 mm. under miotics. Vision 6/7.5. White field 3/1000 35 35 38
28.	53 ♀	Anterior uveitis with old central chorioretinitis. Eye painful, congested. Vascularization of iris sphincter. Corneal precipitates. No posterior synechia.	Fingers at 1 ft.; tension 70, after atropine 50 mm. Hg	Lower 1/2	3 dys. postoperatively, tension 23 mm.; 6 dys., 16; 2 mos., 9; 5 mos., 16. Uveitis quiescent. Vision: fingers at 1 ft.

* Operation not performed by author.

I am indebted to Dr. John F. Gipner for permission to include Cases 15 and 22, and to Dr. Charles T. Sullivan for Cases 17 and 25.

tone of the eyeball was reestablished.

The majority of the cases in this series were in a state of vascular stasis and congestion preoperatively. Following operation, an uncompensated phase was not again observed in any of these eyes.

In cases 24 and 27 (chronic simple glaucoma which had become uncompensated) there was relief from the acute state but they became stabilized at a glauco-

matous level. In these the reelevation of intraocular pressure occurred before the uveitis completely subsided. One is thereby confronted with the problem of whether or not to continue to treat the uveitis in an eye requiring a miotic for the glaucoma.

The operation was most successful in the aphakic group. Tension was controlled in five of the six cases of aphakia that

were secondary to cataract extraction.

The pain, incompensation, and at least part of the irritation were relieved in glaucoma secondary to central venous thrombosis. As the atrophy of the iris became more apparent, the uveitis in these eyes improved. A reduction in the number of new blood vessels upon the iris was not limited to the iris segment corresponding to the treated side of the eye.

Glaucoma with rubeosis iridis in diabetics offers a no less hopeless prognosis. The neovascularization of the iris is a contraindication for intraocular surgery. In the single case (case 8) of rubeosis iridis treated by cyclodiathermy, the tension was controlled, but a later severe proliferating retinosis with an enormous number of new retinal blood vessels led to retinal separation and degenerative changes. Case 28 was a secondary glaucoma with anterior uveitis accompanying extensive vascularization over the sphincter muscle in a distribution similar to that observed in cases of acute rubeosis iridis. There were no posterior synechia. After cyclodiathermy, the congestion and pain disappeared, the tension remained within normal limits, and the uveitis subsided.

In those cases where more advanced

degenerative changes were apparent and in absolute glaucoma, the operation tended to hasten the degeneration.

The possibility of the glaucomatous eye containing a neoplasm must always be eliminated.

CONCLUSIONS

In every instance where cyclodiathermy is contemplated one should not minimize the damage to the integrity of the eyeball, the unpredictable severity and frequently prolonged period of the postoperative uveitis, nor the uncertainty of a permanent control of the glaucoma. The operation is particularly suited to glaucoma where iris vascularization precludes surgery upon the iris, and to glaucoma secondary to central venous thrombosis. In the latter group, tension was not always controlled, but pain was relieved.

Cyclodiathermy may be chosen as an operative procedure for some desperate cases, wherein already proved treatments for glaucoma have failed. It can be recommended in hopeless cases for the relief of glaucomatous pain in preference to enucleation, retrobulbar injection of alcohol, or to the X ray.

STEVENS-JOHNSON'S DISEASE*

A CASE REPORT

W. YERBY JONES, M.D., F. F. TALBOT, M.D., AND WALTER F. KING, M.D.
Buffalo, New York

Stevens-Johnson's¹ disease is comparatively rare. It is generally a pediatric problem, but our case occurred in a patient 56 years of age.

The etiology is unknown.

The onset is somewhat acute, with headache, anorexia, chilly sensations, fever, joint aches and pains. A coryza is often associated, and sometimes a mild bronchitis.

There is a moderate to profuse suppurative conjunctivitis.

The skin generally exhibits macules, papules, and vesicles. The buccal surfaces, the palate, the vaginal mucosa and the glans penis, also may exhibit these lesions.

The white-cell count usually reveals a slight leucocytosis.

The disease appears to be self-limited.

Stevens and Johnson¹ in 1922 reported two cases of eruptive fever with stomatitis and ophthalmia. This condition has since been called Stevens-Johnson's disease or syndrome. It is also known as erythema multiforme exudativa, with stomatitis and ophthalmia. Von Hebra² in 1866 first described erythema multiforme as a skin eruption of macules, papules, and vesicles upon the face, neck, arms, and legs without marked general symptoms. This more rare type, however, has marked general symptoms, fever, malaise, prostration, and other signs, as well as a severe purulent conjunctivitis and stomatitis.

CASE REPORT

B. B., an American housewife born of

*From the Department of Ophthalmology of the University of Buffalo, Medical School and Edward J. Meyer Memorial Hospital.

Irish parents, aged 56 years, was admitted to the hospital, moderately ill.

She had been married for 35 years and had no children.

The personal and past histories had no bearing on the case.

The onset of the disease occurred about 10 days prior to her admission. At first she noticed a muscular soreness of the legs followed by the appearance of an erythematous rash on the tibial surfaces of

Fig. 1 (Jones, Talbot, and King). Lesions on the lips, nose, and eyes.

both legs. The illness was diagnosed by the patient as la grippe and was promptly followed by nasal congestion, sore throat, and a purulent conjunctivitis, with a free conjunctival discharge. Sulfathiazole to be taken orally was prescribed by a private physician, also moist dressings to the legs and irrigation of the eyes with a saturated solution of boric acid. This medication was begun three days before admission. Because the condition did not improve but became progressively worse, the patient sought admission to the hospital (fig. 1).

A digest of the hospital record follows:

The admission temperature was 100° F., rectally; pulse 90; respirations 26, there was an eruption on the skin of the tibial surfaces of both legs (fig. 2). These

Fig. 2 (Jones, Talbot, and King). Cutaneous lesions on the legs.

lesions were chiefly macular, some were papular, and a few petechial. Some areas were discrete, with normal skin intervening. In color they varied from a bright red to a dusky blue. Other areas were confluent. The lips were dry, cracked, and presented some maculo-papular eruptions with an erythematous areola. Lesions of like character were found at the mucocutaneous junction of the nasal orifices. There was marked crusting of mucus to the point of occlusion of the nasal cavities.

The buccal mucosa also presented some small, raised pustular lesions, and a small pustule was observed on the tongue. There was a foul odor from the mouth.

The lymphatic tissue in the pharynx was hypertrophied. The cervical lymph nodes were enlarged but not tender.

The eyelids were swollen, their margins covered with thick pus, and the cilia were matted together. On separating the lids, the eyeball was found to be smeared with

mucopus (fig. 3). The palpebral conjunctivas were turgidly congested exhibiting prominent follicles and small pustular lesions. The bulbar conjunctivas similarly were markedly injected and chemotic with a definite overhanging of a portion of the cornea. The cornea of the left eye presented an old scar about which no history was obtainable. The pupils were moderately contracted and responded adequately in their several reactions.

The iridic structures were not remarkable.

The anterior chambers were not shallow, and the tension was not raised.

The examination of the fundus revealed a moderate arteriosclerotic retinopathy.

The bulbs were sensitive and somewhat painful. The patient complained bitterly of light sensitivity. Visual acuity was markedly diminished. There was no blepharospasm.

No lesions of the vaginal mucosa were apparent.

The symptoms and signs gradually abated. The temperature continued ele-

Fig. 3 (Jones, Talbot, and King). Right eye showing marked injection and chemosis.

vated for a period of 10 days, never more than 102° F., rectally.

The pulse remained elevated throughout the course of illness. The respirations were within normal range.

The ocular, nasal, buccal, and cutaneous pathologic processes receded gradually.

Two weeks after admission to the hospital the patient's vision was O.D. 15/40—2, O.S. 15/30—2. The right eye seemed to be more affected than the left. The purulent discharge had subsided considerably; the chemosis had gone. The conjunctival injection although still quite marked did not have the beefy-red appearance of two weeks ago. During her stay in the hospital, on about the third week, the patient became psychotic. A latent paranoid trend was reported by the psychiatrist. The mental picture has not changed up to the present writing.

The ocular, nasal, buccal, and cutaneous lesions have subsided.

Epithelial scrapings from the conjunctival cul-de-sacs showed no inclusion bodies. Nor did those taken from the vagina and urethra.

Cultures of the conjunctival mucopurulent discharge revealed a heavy growth of *Staphylococcus aureus hemolyticus*. Sedimentation rate was 48 mm. in one hour. The leucocyte count was 15,100; in the differential, the lymphocytes dominated.

The urinalysis was negative as was also the blood Wassermann test. Blood pressure and electrocardiogram were within normal limits. The spinal tap and fluid were not remarkable.

The X-ray studies of the chest, skull, and sinuses revealed no pathologic change.

Penicillin, 2,500 units per cubic centimeter, was used topically in each eye, accompanied by boric-acid eye irrigations and cold moist packs.

REVIEW OF THE LITERATURE

Both cases in the report of Stevens and Johnson¹ were in children aged 8 and 7 years, respectively. There was severe purulent conjunctivitis, fever, malaise, and a fairly generalized skin eruption. In one case the ocular involvement went on to panophthalmitis and blindness in both

eyes. In the other case, one cornea cleared completely, a scar remaining in the other eye. Cultures from the nose and throat yielded cocci and bacilli. Cultures from a papule revealed *Staphylococcus aureus*. Blood culture was negative. There was a mild leucocytosis.

A general blood-stream infection was suspected, without positive evidence.

In 1929 Rutherford³ wrote a paper on membranous conjunctivitis, which is not within the scope of this paper.

In 1931, J. H. Bailey⁴ reported three cases and reviewed the literature on erythema exudativum multiforme for a period of 64 years. He concluded that the disease was caused by some infection of unknown origin and he suggested that the disease was more common than is usually thought to be the case. The quoted references definitely refer to erythema exudativum multiforme, and the fact that the disease may involve the mouth and eyes.

We question seriously whether these references pertain to the Stevens-Johnson disease entity.

Wheeler in 1930⁵ saw a case that ended in the loss of both eyes. His case emphasizes the importance of recognizing the disease, and the serious ocular sequelae which may ensue.

Ginandes in 1935⁶ reported a case in a child 5½ years of age. His case presented membranes of the palpebral conjunctivas and, in our opinion, does not properly belong in the group of Stevens-Johnson's syndrome.

Edgar and Syverton⁷ in 1938 reported two cases in children, aged 12 and 15 years, which showed recurrences and resulted in little ocular damage. These writers were fortunate in having had their cases under observation for a considerable period of time, and investigative work was done on them: A mild leucocytosis was present; blood cultures were sterile, nose

and throat cultures revealed *Streptococcus haemolyticus*, those from conjunctival and mouth lesions showed *Staphylococcus aureus*. Biopsy examination of a lesion revealed a mild exudative to a mild inflammatory reaction. Their investigation failed to show the presence of any infective agent in the serum of the vesicular lesions.

There was some thought that an anaphylactic phenomenon was involved.

Givner and Ageloff⁸ in 1941 reported two cases, one in an adult 23 years of age, the other in a child of 4 years. These writers were unable to find elementary bodies in the vesicular fluid or to develop a virus on chorioallantoic membrane of the chick.

Murphy⁹ in 1944 saw a case in an adult 22 years of age. He expressed no new opinion.

INVESTIGATIVE

We examined epithelial scrapings for some evidence that would point to virus disease. We failed to find inclusion bodies in (1) Daily examination of epithelial scrapings from the conjunctiva, stained by Wright's stain (which also failed to show initial bodies) and (2) in epithelial scrapings from the urethra stained by Wright's stain.

In the fifth week of the disease, 30 c.c. of blood was removed, allowed to stand 24 hours in the refrigerator, then centrifuged and the serum poured off. This serum was sent to Dr. K. F. Meyer, Hooper Foundation, University of California, who examined the serum for the presence of antibodies of the psittacine group of viruses. He reported that the patient's sera fixed complement in the presence of *Psittacosis* antigen in serum dilution 1:32 (4 plus) and 1:64 (3 plus).

DISCUSSION

It is now generally accepted that

Stevens-Johnson's disease is a definite entity. Duke-Elder¹⁰ classifies ocular erythema multiforme into three groups: I. The catarrhal type, which is a mild type; II. The purulent type, a rare type which is more severe than the catarrhal; III. The membranous type, usually the most severe, and the more common, which often produces serious ocular damage. Type II he calls Stevens-Johnson's syndrome.

We believe that the name Stevens-Johnson's disease should be reserved for those cases which present purulent conjunctivitis, stomatitis, and a cutaneous rash, without the formation of a membrane. We were able to find only 11 cases which seem to fall in this group. Our case belongs in this group.

In Givner's case⁸ is found the first report of the disease in an adult.

Our case would seem to have appeared in the oldest patient reported, and it together with two others observed in adults, would definitely indicate that this disease is not confined to the age of earlier childhood.

To avoid confusion as to classification of the disease, it would seem best to continue to apply the name Stevens-Johnson's disease to those cases exhibiting a purulent conjunctivitis, and excluding those with catarrhal or membranous characteristics.

While penicillin was used in the eyes, we have no evidence that it was effective.

Flushing the conjunctival sac and instilling antiseptics may bring about the same result.

SUMMARY

Stevens-Johnson's disease is a rare type of erythema exudativum multiforme. It is a definite entity, and may occur at any age and in either sex. Its etiology has not been determined.

We wish to thank Dr. H. T. Schweitzer for his assistance.

CONGENITAL GLAUCOMA FOLLOWING MATERNAL RUBELLA*

REPORT OF TWO CASES

DuPONT GUERRY, III, M.D.

Richmond, Virginia

The timely report of Reese¹ in this country and of Gregg² in Australia concerning congenital cataract following German measles in the mother has occasioned widespread interest and has resulted in bringing to light many cases whose etiologic background would have otherwise remained obscure. In these reports as well as that of the National Health and Medical Research Council of Australia³ other congenital anomalies such as heart disease, microcephaly, microphthalmia, feeble-mindedness, deaf-mutism, and hypospadias were found occurring concomitantly with the cataracts, but of all the cases reported only one is said to have had congenital glaucoma. The recent occurrence in the author's private practice of congenital glaucoma in two children whose mothers suffered from an attack of German measles during early pregnancy suggests that such an anomaly may also be a common sequela of German measles, and that careful inquiry into the history of all cases of congenital glaucoma may reveal the rubella taint in many cases. The literature pertaining to this problem has been adequately reviewed by Reese.

CASE REPORTS

Case 1. R. J., a boy, 3 years of age, a private patient of Dr. Lee Sutton was admitted to Medical College of Virginia Hospital on January 25, 1945. Delivery had been spontaneous, without undue trauma, and the birth weight was 7½ pounds. Family history was negative ex-

cept for the mother's having had German measles between the first and second months of pregnancy. From birth the child was mentally retarded. He walked when supported at two years but never learned to talk. A convergent squint had been present from birth as had congenital cataracts. Shortly after birth wandering nystagmus appeared. The child had always been a feeding problem and for the six months preceding hospitalization he had constantly lost weight and strength. In addition, spasticity of the leg muscles was noted, and a constant side-to-side rolling of the head developed. The diagnosis of rickets was made and treatment for this was instituted by the family physician. When, in spite of treatment, the child became progressively more spastic, and decubitis ulcers developed, meningitis was suspected, and the child was referred to Dr. Sutton for diagnosis and treatment.

At the time of admission the following abnormalities were noted on physical examination: Marked malnutrition; congenital cataracts and convergent squint; alopecia areata, occipital region; generalized lymphadenopathy; marked dental caries; questionable Harrison's groove and rachitic rosary; slight tremor of hands; blowing systolic murmur at apex; spasticity of leg muscles; pale mucous membranes; decubitis ulcers over buttocks; weight, 17 pounds.

Except for a severe hypochromic anemia with marked red-cell regeneration and pseudomacrocytosis, and a leucocytosis of 25,000 with myeloblasts, promyelocytes, and occasional normoblasts, the

* Read before the Virginia Pediatric Society on June 8, 1945.

laboratory findings were normal. Skull X-ray studies revealed moderate convolitional atrophy. The diagnosis of congenital idiocy, congenital cataracts, malnutrition, and hypochromic anemia was made and the child placed on a high-caloric, high-vitamin diet. Transfusions were given and ferrous sulfate prescribed for the anemia.

Eye consultation revealed the following changes: The patient followed light. The eyes were microphthalmic. There was a convergent squint of 40 degrees Hirschberg, with wandering nystagmus. Moderate bilateral corneal edema was observed in the central portion, more in the left eye than in the right. The corneas measured 10 mm. The anterior chambers were shallow. The pupils were moderately dilated and fixed; the lenses showed fairly dense nuclear cataracts with clear cortex. The fundi gave a good reflex. The patient was too uncoöperative for detail. Tension was 4+ to fingers. The impression was: 1. Convergent squint. 2. Congenital glaucoma. 3. Congenital cataracts. 4. Microphthalmia.

Examination of the eyes was then carried out under ether anesthesia. A fair view of the fundi was obtained and extreme glaucomatous cupping was found. Fairly dense cataractous changes confined to the nuclear region were also present. Tension with the Schiøtz tonometer (7.5-gram weight) was over 40 mm. in both eyes. An attempt was then made to carry out an iris-inclusion operation on the right eye. Immediately on opening the globe with the keratome, the cornea cleared but when an attempt was made to grasp the iris with forceps it was found to be friable and bound down firmly to the lens so that incarceration was impossible. A modified Lagrange operation was therefore carried out by punching out a portion of the anterior scleral lip with the Castroviejo punch. Following

the operation filtration was established and the tension well controlled.

At a later date a similar operation was carried out on the left globe. In this instance, however, little corneal clearing resulted.

Shortly after the last operation the patient developed chicken pox, which necessitated his isolation. In spite of this he improved progressively and when discharged on April 15, 1945, his general condition was much improved and his intraocular pressure was normal to fingers. The patient is to return in the near future for needling of the cataracts.

Case 2. B. C., a white girl aged 3 years, was brought for ophthalmologic attention on April 14, 1945, because of a "large left eye which keeps getting bigger." Birth had been spontaneous, and no abnormalities were noted at that time. Her birth weight was 7 pounds. The family history was negative except for the mother's having had a moderately severe attack of German measles between the second and third months of pregnancy.

About five to six months postpartum, the parents began to notice that the left eye was "getting bigger." Nothing was done about the condition until the child was three years old, when the affected eye had become unsightly. Useful vision had never been present in the left eye.

Physical examination except for the eye findings was entirely negative.

Eye examination revealed the following changes in the left eye. The right eye was normal. Vision, O.D., follows light well. No coöperation for "E" chart; O.S., No light perception. Externally the left eye was prominent and cornea large (14 mm.), with numerous horizontal ruptures of Descemet's membrane. The pupil reacted consensually but not to direct light. The muscle balance was normal. Tension O.S. was 3+ to fingers. The

anterior chamber was very deep; the fundus showed a pale disc, with deep cupping and vessels pushed nasally.

Examination under ether followed by iris inclusion was advised, but the parents have so far refused to allow these procedures to be carried out. An interesting sidelight in regard to this case—and totally without confirmation—concerns the history. The mother stated that at the time she had rubella two of her friends whose pregnancy was of about the same stage as hers also contracted the disease. When they came to term, one gave birth to a "blue baby that died after two days"; the other gave birth to an infant which had "a big eye just like my child's." Since that time the friend whose baby had the "big eye" has moved elsewhere and she has consequently lost contact with her.

DISCUSSION

The clinical evidence at hand allows no modicum of doubt that congenital cataract as well as other anomalies can follow in the wake of maternal rubella. The cry of "post hoc" type of reasoning cannot be raised here, for already cases in this country and abroad are sufficiently numerous to rule out the operation of simple coincidence. When further data have accumulated it may well be that congenital glaucoma will be found to be a more frequent sequela of this disease than is indicated by the report of only one case in the entire Australian series. In that series, while there was only one frank case of buphthalmos, three other cases of corneal clouding, highly suggestive of glaucoma, are mentioned. Since congenital glaucoma, although present at birth, is frequently not diagnosed until later and even then at times diagnosis may be extremely difficult, it is not unlikely that cases from this series have since appeared and will eventually be reported. This is well illustrated by the second case report.

In this instance the signs of buphthalmos were not noticed until the child was at least six months old. On the other hand the Australian epidemic may have had a particular penchant for cataract formation whereas other epidemics may result in anomalies of another character.

There has been considerable discussion as to whether or not the maternal rubella responsible for the congenital anomalies cited is the time-honored disease, some variant, or perhaps an entirely new entity. As yet this question also remains unanswered. From reports thus far, though, it appears that the disease responsible is rubella and that only recently have we realized its full potentialities. Indeed there is an old-wives' tale, well known amongst the laity, to the effect that "if a mother has German measles while pregnant it will settle in the baby's eyes." Here again we may find operative the principle that superstitions many times precede medical thought by centuries—as in the case of the old Mosaic law postponing circumcision until the eighth postpartum day when the prothrombin concentration has reached a safe level—only to receive scientific backing in this "enlightened" century.

The question as to what is the best method of handling these cases is an important one. Primarily, our efforts should be expended in preventing maternal rubella by such procedures as strict isolation of expectant mothers during an epidemic and by the use of convalescent serum in those exposed. If, in spite of these measures, rubella develops during the first two months of pregnancy therapeutic abortion should be seriously considered and the prospective mother should be given the facts and allowed to make her decision.

In those instances wherein a defective child has been born the particular anomaly present must be treated. If cataract alone

is present, needling should be carried out as soon as the infant's general condition permits; if glaucoma is present, an iris-inclusion operation followed by massage should be the method of choice, and if cataracts are present, needling should be postponed until the tension is controlled.

SUMMARY

Two cases of congenital glaucoma following maternal rubella during the first and second months of pregnancy are reported.

HETEROGENEOUS CONJUNCTIVAL TRANSPLANTATION*

EMANUEL ROSEN, CAPT. (MC), A.U.S.

Heterogeneous conjunctival transplantation offers many possibilities in ophthalmology. Great impetus has been given this procedure through the remarkable research of Russian workers in the field of tissue therapy. They have uncovered an entirely new phase of medicine and surgery almost as startling in approach and as breathtaking in scope as the historical contributions of Pasteur and Lister.

One of the foremost of the Russian ophthalmologists, V. L. Filatov,¹ for the past 10 years has been grafting animal tissues, particularly conjunctiva, refrigerated for several days before transplantation. He suggested that the tissues be removed under strict asepsis within 10 hours after death and transferred to a dry sterile bottle which should be kept at a temperature of 2 to 4°C. for seven days. He has shown that at the end of

this time any spirochetal infection will have totally disappeared. Substances which stimulate biochemical processes known as "biogenic stimulators" seem to accumulate in these refrigerated tissues, which can be transplanted more effectively than fresh tissue. Filatov has shown that these "biogenic stimulators" occur in many tissues, amongst which conjunctiva is included. The tissues are usually stored with the underlying subcutaneous structures but are freed of excessive elements at the time of transplantation.

Case report. The patient, a man aged 26 years, had incurred a very severe lime burn when he was 12 years old. The eye remained inflamed for several months, the process terminating in a very dense, vascularized corneal scar through which none of the inner structures of the eye could be observed. The upper lid was adherent to the globe, producing a ptosis. Light projection was faulty. The eye was constantly red, somewhat divergent, and teared readily in light. Many vessels ran

* Owing to the author's assignment to overseas duty, his corrected proof has not been available.

Fig. 1. (Rosen). Appearance of the left eye before operation. The adhesion of the upper margin of the tarsus to the eyeball proper makes it quite difficult to evert the lid.

throughout the substance of the cornea, which was somewhat thickened in cross section. The patient was referred from another hospital for enucleation, but because of the adhesion of the upper lid to the globe it was apparent that an attempt at a plastic repair should first be made before enucleation was considered. Oral mucous membrane was at first suggested as transplant tissue but cadaver conjunctiva became available at about this time and its utilization was undertaken.

Local anesthesia was administered (2-percent butyn alternated with 4-percent cocaine) and the adhesion which existed between the upper border of the upper tarsus and the conjunctiva just above the limbus was severed along a horizontal line. Upon completion of this dissection a spindle-shaped defect in the conjunctiva became apparent through retraction and release of the adhesion. The exposed defect was approximately 20 by 16 mm. in area. A similarly shaped piece of conjunctiva was cut out of the donor's conjunctiva. Two anchor sutures of 4-0 silk were placed at the terminals of the spindle, which was turned upon its episcleral surface and then thinned down to a minimal thickness. One end of the

spindle was then anchored to the corresponding angle in the eyeball and sutures were inserted along the upper and lower edges with 6-0 silk. The overlapping tissue was trimmed down before the final suturing was made to the external angle of the spindle. The flap was not stretched. Sulfathiazole ointment (5 percent) was placed in the cul-de-sac, following which an alginate substance was poured into the socket which rapidly hardened into a very efficient and rather thick stent. The eye was covered over with a tight pressure bandage which was retained for four days. At the end of five days the alginate stent, which now resembled a rubberlike mold of the conjunctival sac, was removed. The graft appeared to be in good position and of good color. Upon the thirteenth day postoperatively the patient complained of pain in and about his left eye, and it was observed that the right upper lid was edematous. Inspection of the flap showed a hemorrhage beneath the graft. A strong pressure bandage was applied to the left eye for 72 hours. Upon removal of the dressing the edema of the lids and the hemorrhage were seen to have disappeared. On the 25th day there was no indication of any complication, the

Fig. 2. (Rosen). The appearance of the left eye six weeks after operation. The tarsus is no longer bound down to the eyeball and the lid can be readily everted. An upper cul-de-sac is now present.

Fig. 3 (Rosen). Steps in the operative procedure. a, Adhesion of tarsus to eyeball. b, Adhesion is severed with scissors. c, Oval defect resulting from retraction of the adhesion. d, Donor's conjunctiva placed in defect left after separation of adhesion. e, Conjunctiva sutured in place. f, Appearance of eye upon completion of operation.

hemorrhage had become absorbed, and there was little indication of the point of attachment of the graft. Five weeks after the transplantation the flap had thinned out, leaving no marked elevation nor scar formation at the site of union of donor's and recipient's conjunctiva. At about this time it became apparent that not only was the transplant successfully adherent but the vascularization and corneal scarification were less marked. The patient thought that he was able to perceive light better than he had prior to the transplantation, although check-up showed that light projection was still faulty.

Although Filatov allows the sutures to remain only 24 hours, in our case they were kept in much longer. Von Hippel² had noticed that in many cases a clear corneal graft leads to a clearing of the surrounding leukoma, and upon the basis of these observations Filatov began to use his cadaver cornea, subsequently developing the new field of preserved tissue and its usage.^{3,4}

From this single case report it is conceivable that cadaver conjunctiva in refrigerated and unrefrigerated form may be used for a great many conditions.

A CONTINUATION OF THE SCREEN TEST

HILMAR G. MARTIN, M.D.

Milwaukee, Wisconsin

Ocular-muscle functions are, as a rule, considered "normal" when a state of so-called balance exists. Variations from the normal, or "imbalance," seem to have achieved classification more often by the extent of the variation than its nature.

"Normals" are not expressions of absolute values but of a vast average measure serving as a basis for comparison.

Discussion of one phase of this subject must take whole functions into account. Clinical proof of the functional value of separate muscles will be wanting because all other contributing actions cannot be rendered known or even constant while the single variable is investigated.

Successful treatment is based upon accuracy of diagnosis and the responsive properties of tissues.

In recent years the screen test has come into constant use because of its accuracy, simplicity, and objective nature. It enables the examiner to define the overactive or underactive eye as well as the particular system involved.

Perhaps the most common varieties of imbalances, influenced by refractive errors, are those of convergence and divergence.

Methods of measurement defining imbalances in these two directions are at variance in regard to terminology rather than actual meaning. Terms defining the nature of muscle action and the measure by which it is taken must be stated. Positions of rest, of fixation, of usual regard, and of maximum function are often loosely applied. Obviously they do not mean the same thing nor do any of these terms used separately and properly give

adequate information of imbalance in any given case.

The apparently simple action of convergence and divergence alone is really accomplished by a complex process of action involving all of the muscles. Some are concerned with primary action, some with synergetic action, and others with antagonistic action.

The method of testing ocular-muscle balance offered here was originated in an effort to extend the information given by the usual screen test and to define more specifically the underlying causes of lateral imbalances.

This method offers information with regard to convergence and divergence values and as to whether the anomaly is influenced largely by accommodation elements or is due to inherent inability of muscular response; it also indicates which eye is the greater offender. It shows, moreover, whether the convergence is normal, or if insufficient, whether the divergence faculties are excessive to render the convergence relatively underactive. One eye may tend to overconverge because its fellow does not turn in enough. If the deviating eye is always adjudged the faulty member and treatment is directed toward the reduction of its overactivity, the resultant might well provoke a semblance of balance by reducing the general operation of the complete system of action.

METHOD

The near point of binocular convergence (PpC) is determined and recorded in the usual way.

The patient is now required to fixate the test object, a tiny bulb flash light, brought slowly toward the bridge of the

nose *past* the point previously determined for PpC. This is called the "Light convergence test" and is referred to as the L. C. test.

The normal responses to the L. C. test are that: 1. Both eyes continue to converge maximally when the light has been approached closer than the previously noted PpC and even up to the bridge of the nose, or 2. Most usually, both eyes cease to converge at the same time and hold this position even though the light is continued in its approach, or 3. Both eyes diverge slowly and *equally* to the global midline or very slightly beyond, but to the *same* extent, even though the light is continued in its approach past the break point.

These responses have been noted if the muscles are in balance by other usual tests.

In cases of imbalance a point of approach of the light will be reached where *one* eye will cease to converge and proceed to rapid divergence to the global mid-line or beyond while its fellow continues to hold in the converged position or even continues to converge still more.

The underacting internus of the diverging eye is not yet incriminated as the chief offender, nor is this action always in agreement or compatible with the results of other muscle tests. This is only a step toward evaluation of the contributing muscles in convergence activity.

Conversely, an apparently overacting internus, as defined by other muscle tests, may show underaction by the L. C. test.

In order to reconcile these differences another test was devised known as the "Monocular convergence test," referred to as the M. C. test. The L. C. and M. C. tests complement each other.

The M. C. test is based upon the observation of Donders, well over 100 years ago, that when one eye was screened and a minus lens placed before the free eye,

the screened eye turned inward. The minus lens before the free eye induces increased accommodative effort, thereby increasing the convergence.

In Donders's experiment the station of the test object was fixed and the minus lens strength before the free eye was increased.

The M. C. test reverses this procedure in that the test-object distance is varied and the lens strength is maintained constant while the reaction of the screened eye is being observed.

Before any lens is placed before the free eye the test is performed in this sequence:

One eye is screened and its responses noted as the light progressively approaches, just as in the L. C. test. Normally the screened eye will diverge to the global mid-line when the test light reaches a certain proximity. If, however, the screened eye diverges past the global mid-line, and when the test light is still quite remote, a minus lens of known strength is placed before the free eye in the effort to restrict the screened eye from diverging beyond the global mid-line. The lens strength is progressively increased until the screened eye stops its divergence when the global mid-line is reached. The strength of the minus lens before the free eye, which is just sufficient in amount to induce the screened eye to hold to the global mid-line, is taken as the measure of accommodative stimulus necessary to maintain normal convergence.

Each eye is tested in the same manner and comparison is then made of the strength of minus lens necessary to limit the screened-eye divergence to the global mid-line area. It must be remembered that the screened eye is the one under test in its failure to converge normally, and that the minus-lens strength is the measure of the accommodative contribution to convergence.

If the PpC tests are within normal limits and the near screen test possibly shows esotropia, but the L. C. and M. C. tests show convergence insufficiency, the accommodation is functioning normally within the usual work distance (up to PpC limits) and the fault lies inherently in the convergence muscle structure.

If the PpA is greater than normal and the PpC is low (remote) there usually is an accommodative spasm (increased tonus) to stimulate the low PpC to better effort. The accommodative effort must be greater to stimulate the underacting convergence. For hyperopic persons, the use of a high or full plus correction to bring the accommodative effort to normal for age and decentering the plus lens in to give base-in prism effect, helps the underacting convergence.

In convergence squint or dominance, the M. C. test will probably show that the convergence muscles give a normal response. However, the overconvergence may be responsive to overstimulation in order to counteract an actual divergence-excess tendency. The spontaneous convergence picture binocularly is a symptom rather than a condition. Any treatment designed to lessen the overactive convergence or excess is misconceived if the primary fault is not in the convergence mechanism.

The binocular-test arrangement seems to be the factor that brings out the deviations, for, observed under occlusion cover with correction in place, the dominant eye is most usually straight or follows the direction of gaze of the fellow eye.

Treatment must be directed toward the creation or reestablishment of usual balance by such means as will stimulate an underacting system to greater responsive actions. Treatment directed at minimizing overactive mechanisms of functional order may produce a semblance

of balance merely by reducing the general operation of the complete system of action. Exception to this is in order where stimulation of underaction is subject to mechanical limitations to the extent that balance cannot be effected otherwise.

Merely reducing activity, or understimulating a normal function, is not cogent to a concept of treatment except by "weakening." Reducing convergence excess by high plus lenses, or radically by surgical recession, is not by any means "weakening" a muscle. The true response to such treatment is underaction physiologically, or mechanically, through leverage. Conversely, imposing a minus lens, or resection for divergence tendencies or conditions, does not strengthen a muscle, but merely gives greater advantage to the part in its usual process of function.

Symptoms in muscular anomalies are not proportionate to the amount of variation from the normal. Smaller errors cause a variety of troublesome symptoms while large errors often occasion but little discomfort.

SUMMARY

A method is offered as a continuation of the usually performed screen test, which aids in defining the offending mechanism in conditions of variation from accepted normal balance.

Used with other muscle tests for near, these tests afford information regarding the values of the most important contributors in the combined function of vergence.

The objective nature of the tests permit use upon the uncoöperative patient as well as the very young.

Defining the mechanism to which treatment should be directed offers a safeguard against inducing anomalies of opposite nature, in the attempt to achieve balance.

NOTES, CASES, INSTRUMENTS

NOTE ON THE INCIDENCE OF CLINICALLY SIGNIFICANT ANISEIKONIA*

H. M. BURIAN, M.D., RITA WALSH, B.S.,
AND R. E. BANNON, B.S.
Hanover, New Hampshire

Often it is asked, "How frequently does aniseikonia occur in the general population?" This question is as difficult to answer as would be similar questions regarding errors of refraction or heterophorias. Aniseikonia is as general as are the errors of refraction or the heterophorias, and similarly it can be measured in almost every individual.

The question must be rephrased so as to ask, "What is the frequency of *clinically significant aniseikonia*?"¹ One may say that an aniseikonic error is clinically significant if there is a difference of at least 0.75 percent between the ocular images, and if there are sufficiently severe symptoms associated with the use of the eyes which cannot be attributed to other causes. In such cases we believe that a correction for aniseikonia is warranted. The frequency of clinically significant aniseikonia in the general population is difficult to determine satisfactorily, and so far only estimates have been made, which vary widely.

In an effort to answer the question of the incidence of clinically significant aniseikonia, we are reporting upon the statistics gathered in the town of Hanover, New Hampshire, where the Dartmouth Eye Institute is located. This town, in many respects, offers a satisfactory sample of the population for such a statis-

tical study. It is not near any large city, where some inhabitants would go for eye care; it is a college town, and so a large proportion of its residents use their eyes strenuously, and most of the residents can afford good eye care. All the aniseikonic tests were made in one place and the data for a 15-year period are available. Although all inhabitants who had general

eye care were not seen at the Institute†, a large proportion of them were examined here. Obviously, Hanover is not typical of rural or industrial communities. Furthermore, since the work originated here, the community is probably more conscious of aniseikonia than would be the people of some other town.

† Until the onset of the war the local clinic (Hitchcock Clinic) had one eye specialist who provided general eye care for a large number of Hanover residents. Also, a few of the residents undoubtedly consulted optometrists in neighboring towns.

* From the Clinical Division of the Dartmouth Eye Institute, Dartmouth Medical School.

This report of aniseikonic examinations pertains only to the permanent residents of the town and does not include any of the college students. Two groups of patients must be distinguished in the study: those who came to the Institute at their own initiative because of ocular symptoms, and those who volunteered as subjects in the training courses for aniseikonic clinicians. The majority of the latter group had no symptoms.

From 1929 through 1943, 699 Hanover residents were examined for aniseikonia. The number examined in the two groups, as well as the number for whom aniseikonic corrections were prescribed is given in table 1. The population of the town has been taken as 3,234, which is an average of the population figures given by the United States Census for the years 1930 and 1940. This figure includes about 700 children, of whom very few were examined for aniseikonia.

Thus, 699 Hanover residents, or about 21 percent of the population, were given aniseikonic tests. Of these, 320, or 10 percent of the population, were regular aniseikonic patients; while 379, or 11 percent, were subjects used in the training courses. Of the regular patients, 135 were given aniseikonic corrections. This represents 42 percent of the patients examined, or about 4 percent of the total population. Of the subjects used for practice and demonstration in the training courses, only 31, or 8 percent, were given aniseikonic corrections; and this is about 1 percent of the total population. Thus, 166, or about 24 percent of the 699 persons examined, were given aniseikonic corrections. The 166 individuals given aniseikonic corrections represent about 5 percent of the population of the town.

A recent study² of the results obtained with 2,115 patients given aniseikonic corrections indicates that about 70 percent

of the patients experienced complete or partial relief of their symptoms. This is in good agreement with the figures published by several previous observers.³ If in the classification of *clinically significant aniseikonia* we include only those patients whose symptoms were relieved by aniseikonic correction, the percentage of the population of Hanover having clinically significant aniseikonia is 3.5 percent (70 percent of the 5 percent of the population who were given aniseikonic corrections).

Summary and Conclusions. In an attempt to answer the question of the incidence of aniseikonia, a study has been made of the clinical data in the town of Hanover, New Hampshire. The results were as follows:

Average population, 1930-1940—3,234.

Total number of residents examined—699, or 21 percent of the population.

Number of regular patients examined—320, or 10 percent of the population.

Total number given aniseikonic corrections—166, or 5 percent of the population.

Estimated number of patients benefiting from the aniseikonic corrections—116, or 3.5 percent of the population.

These figures may not be representative of other communities, and the improvement in the technique of measuring aniseikonia, the simplification in instrumentation, the reduction in examination time and in the cost of aniseikonic lenses may bring about less conservatism in the examination for, and the prescribing of, aniseikonic corrections. Post⁴ stated: "Thus the aniseikonic clinics have become the rendezvous of the most difficult patients for whom to obtain comfort. That anything good is accomplished for these patients is the miracle." He recommended that the tests for aniseikonia be simplified so that the examination time could be

shortened, and also advised that the cost of the lenses be reduced. These are the current aims of the Dartmouth Eye Institute, and it is hoped that once they are realized the incidence of clinically significant aniseikonia will be studied again.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

January 8, 1945

DR. MILTON L. BERLINER, *presiding*

DARK VIOLET LIGHT FOR MICROSCOPIC INSPECTION AND PHOTOGRAPHY

DR. ERNEST METZGER has been using this method as a diagnostic aid since 1924. It is applied with or without a fluorescein solution. He demonstrated the normal fluorescence of the clear lens and the appearance of pigment and fat in the anterior segment of the eye. He also presented stereoscopic photographs of the eye taken with this light.

CAMPIMETRY WITH ULTRA-VIOLET LIGHT

DR. GEORGE KLEEFELD demonstrated visual-field testing with ultra-violet light. In campimetry, and especially stereocampimetry, fluorescent targets together with fluorescent markings on the posterior surface of the perimetric arc permit the determination of the fields of vision in darkness. The delimitation of the blind spot is unusually accurate by this technique.

VISUAL EXERCISES IN OPHTHALMOLOGY

DR. JOSEPH I. PASCAL presented a paper on this subject. His theme was that visual exercises, using the term in the broadest sense, are bound to form a larger part of ophthalmologic practice in the future than at present. Starting with exercises to improve the visual acuity in an amblyopic eye, he stressed the fact that the resulting improvement is largely due to the psychic phase of vision. The process of training is largely educational,

teaching the mind to make better responses. An extension of this procedure is to teach the mind to appreciate better nonfocused retinal images. This can be done to a certain extent, although the procedure is overexploited by some non-medical practitioners. The principles underlying these exercises involved the application of movement, color, and some bodily activity.

He spoke of exercises for (1) the improvement of peripheral vision and its importance; (2) improving color perception in the light of established facts; (3) improving the rate of reading; and (4) improving the speed and span of the visual act. The latter is in line with the modern psychological concept, the so-called "Gestalt psychology" which postulates that we learn by "synthesis" rather than by "analysis."

Dr. Pascal then reviewed the exercises for improving neuromuscular coordination of the eyes in the act of binocular vision. He mentioned the red-glass test as a means of judging whether or not any neuromuscular incoordination requires immediate attention or not. For these exercises he stressed the fact that they can be given without elaborate apparatus, if need be. Simple prisms will provide rhythmic or sustained exercises, sometimes by means of the step method, sometimes the sliding method, or a combination of these. Variety and interest are all important. In addition, even the use of a simple stereoscope will help greatly, especially if it is used with the Pointer method, which, he said, he described some 12 years ago.

As not many ophthalmologists may be fitted by temperament to engage in this

work directly, since it is largely in the nature of teaching, Dr. Pascal suggested the employment of trained orthoptic technicians. These technicians are usually women, have more tact and patience for teaching elementary skills and are most suitable to administer these various exercises under the supervision of the doctor.

Discussion. Dr. James W. Smith asked for more information regarding exercises in color-blind patients. Men, rejected for military service for this reason, inquired about a clinic in Brooklyn which could cure their defect. An editorial in the J.A.M.A. of June 5, 1943, stated that the claim of the optometrist Lepper of an alleged cure for color blindness was unwarranted and that he was conducting an educational rather than a therapeutic process. An intelligent patient can memorize the plates used in the Ishihara test. One color-blind patient seen by Dr. Smith even trained himself to give the correct answers for the pseudo-isochromatic plates if they were presented to him in regular sequence. However, if half of the plate was blocked out or turned upside down, the patient's answers were again those of a color-blind individual. Dr. Pascal has been discussing temporary color retraining rather than visual exercises.

Dr. Daniel Rolett acknowledged the importance of visual training in the amblyopias or for poor development of the visual sense or reading ability. However, a patient of his, rejected by the Merchant Marine because of color blindness, attended a private clinic in Brooklyn to cure this defect and then applied for admission to the Marines where he was accepted. He returned to see Dr. Pascal, who presented to him the Ishihara test, all numbers of which he read easily. However, when shown an old set of German

plates he was unable to read them and admitted having memorized the Ishihara chart. Another patient went through this same "training" with the same effect.

Dr. Morris Jaffe said he considered the retraining of diminished visual acuity and defects of color perception fraught with dangerous possibilities. He described a patient with primary optic atrophy associated with cerebrospinal syphilis. The patient and his wife were informed of the poor prognosis and were advised that he should learn Braille and have occupational training to become self-supporting. Instead, Christian Science healing was undertaken. Six months later, when the patient was reexamined the findings were unchanged, but he and his wife were certain that his vision was restored and proved the point by telling exactly the time on a clock on a bookcase. However, when the hands of the clock were pushed back a half hour, he could not tell the changed time, nor could he count fingers at 12 inches. The patient had adjusted himself to his condition, but still could not see the physical world about him. He later admitted he would be happier if he could learn some useful work.

The psychologic approach of reeducation to enhance visual and color perception will only stimulate charlatanism from those who have no adequate specialized medical training in the field of ophthalmology. This therapeutic aid, as suggested by Dr. Pascal, must be received with caution and critical judgment.

Dr. Pascal concluded by stating that he had not done much work in the field of retraining of color vision but has been in correspondence with people who have and for whose honesty he can vouch. They have obtained results not explained solely by memorizing. Many of their patients have acquired a system of recognizing colors, probably in some other manner.

The methods vary with different men. One merely has to impress upon an individual a certain color. One method, as a starter, is to show the individual three primary colors in bright saturated discs and let him look at them intently until he can recognize each of them by name. The training cards are then reduced in size and brightness and some explanation of "shades" and "tints" is introduced. There is more to this process than memory.

Dr. Pascal said he had no experience with the use of vitamin A in color rehabilitation, but greatly doubts its efficacy except where there is a general systemic lack of vitamin A.

Regarding improvement of visual acuity by training, the case of an 18-year-old girl was described. She had been given exercises in order that she might stop wearing glasses which were given her at the age of 9 years and which she managed to do without most of the time. On the Snellen chart the uncorrected vision was between 20/30 and 20/40. Objective examination indicated about 2 diopters of myopia and subjectively, on unfamiliar picture charts, the visual acuity corresponded to the refractive error. Nevertheless, she read 20/30 to 20/40 on the conventional charts. Her sight for things about the room was definitely better than that of a person with 2 diopters of myopia who regularly wears glasses and then removes them. In other words, this was an individual who disliked wearing eyeglasses, wore them only occasionally, and consequently trained herself to see fairly well without glasses even before she went to this practitioner for special aid.

Dr. Pascal agreed that charlatanism is indeed a problem and that this field, like all new fields, is apt to be exploited. It is therefore important for ophthalmologists to investigate it and adopt whatever is of benefit in their work.

PRACTICAL POINTS IN PRESCRIBING BIFOCALS

DR. ARTHUR LINKSZ said that comfortable near vision through bifocals depends on more than proper refraction and the choice of an adequate reading addition. Habits, occupation, and number of optical and mechanical factors must be taken into consideration. The optical properties of some bifocals were described and it was pointed out that Benjamin Franklin's original bifocal, although cosmetically undesirable, is at the same time optically one of the best types yet devised. The prismatic effect, because two separate lenses are used, is very low and there is no distortion nor color difficulty in the reading portion.

One of the most widely used bifocals today is the one-piece variety. The so-called "A" one-piece bifocal is an excellent lens and may be used with strong plus lenses and with weak additions; the optical center of the reading portion is about 8 mm. below the distance center. When a minus lens is worn, there is a great base-down prismatic effect with this bifocal, and on looking through the lower portion the floor seems far higher than it should. In these cases a "B"-type segment is called for, and this, with its small radius of curvature, and higher center of curvature, will minimize the displacement. Formulas were presented for making the various calculations regarding these lenses, their size, and the location of their optical centers.

Discussion. Dr. Joseph I. Pascal pointed out that the Franklin bifocal is a single-center lens, the two components being divided along the optical centers, which are placed adjacent to each other. The idea of having the optical center of the upper part 4 mm. above the dividing line, and the optical center of the lower part 4 mm. below the dividing line came in

long after Franklin's death. The latter bifocal is a bicentric bifocal, whereas the original Franklin lens was monocentric. Probably if Franklin had invented a bifocal lens with two optical centers, bifocals would not have been so rapidly adopted. The important point is that his lens had only one optical center, so that the image of any object was always formed along one axis. This is the real point, image formation along one principal or secondary axis. Dr. Linksz discussed only one type of bifocals, probably for lack of time, but there are, of course, many other types, fused bifocals, and so forth.

Dr. Linksz agreed that the original Franklin bifocal had only one optical center but had not discussed the lens because of time limitations. He emphasized that this two-piece type of bifocal can be made with two optical centers, each in its proper place and so be free of prismatic effects. The so-called "jump" caused by bifocals with two optical centers instead of one, is no disadvantage, and in fact is never noticed by the patient, as the eye does not register while moving over the dividing line. The original Franklin bifocal with one optical center, while free of "jump" has a prismatic effect both at the far and reading points. Bifocals should be constructed so as to have optimum optical properties 4 to 6 mm. above and below the dividing line. While there was no time to discuss fused bifocals, the various mathematical considerations presented are valid both for the fused and one-piece types.

EXAMINATION AND CORRECTION OF ASTIGMATISM

DR. I. S. TASSMAN said the examination should commence with an accurate history and a careful analysis of the complaints with consideration of the subjective symptoms, age, and occupation; then

these factors should be evaluated as to their connection with a possible refractive error. Headaches should be studied: their situation; whether they appear during the day, especially while the patient is at work or at school. Panoramic headache should make the examiner consider asthenopia. When determining the visual acuity, note which letters are correctly called and which are miscalled; these give an indication as to the type of refractive error.

In all cases with active accommodation a cycloplegic should be used. Atropine, 1-percent solution, and paredrine, 1-percent solution, are used for children; after 13 years of age, homatropine, 2-percent, and paredrine, 1-percent, are used. In performing the retinoscopy, examine the central area by having the patient gaze at the light; children should keep their heads straight. Neutralize first one principal meridian to convert the error to simple astigmatism and then use a cylinder to neutralize the remaining band of light. A subjective examination should follow the objective test. All cases in which a cycloplegia is used should have a post-cycloplegic examination, at which time the strength of the sphere may change; the strength and axis of the cylinder is not frequently changed. The use of a cross cylinder is helpful in accurately determining the axis.

If an older patient is receiving his first cylindrical correction, when the latter is of a high degree it may have to be reduced; children are given the full strength. The fitting is important, especially for high cylinders, oblique axes, and for the presbyopic subject wearing bifocals.

Discussion. Dr. J. H. Bailey disagreed with the claim that the combination of paredrine and homatropine produces greater cycloplegia than homatropine alone. He believes that under like condi-

tions the cycloplegia produced by 5-per-cent homatropine solution is not increased by the addition of paredrine.

Paredrine is a sympathomimetic drug, and, as such, must be an exciter or an inhibitor of certain smooth muscles. It is asserted that paredrine acts upon the ciliary muscle in a manner analogous to its action on the dilator pupillae, which, in turn, postulates a dual innervation of the ciliary muscle, sympathetic longitudinal fibers (Bruecke's muscle), and antagonistic parasympathetic circular fibers (Muel-ler's muscle). The longitudinal component supposedly causes flattening of the lens, rendering the eye hypermetropic whereas the circular component increases the curvature of the lens, adapting the eye for near vision.

In the first place sympathetic fibers going to the longitudinal muscle cells have not been isolated or identified. Secondly, it is very much disputed that sympathetic excitation by stimulation of the cervical sympathetics results in a flattening of the lens. Furthermore, the word cycloplegia connotes a relaxation of the entire ciliary muscle and not one part contracted and the other part inhibited.

Static refraction means the refraction of the eye in repose. Obviously if paredrine excites a part of the ciliary muscle, the eye is not in repose from the standpoint of refraction. Furthermore, the procedure usually performed to determine the residual accommodation, which, in turn, is the measure of the adequacy of the cycloplegic, leaves much to be desired. The examiner should make an allowance for such factors as the mydriasis, the angle subtended by the test object, and the several psychologic variables. The ophthalmologist must also bear in mind that the extent of the cycloplegia is influenced by the nature of the vehicle containing the drug. Homatropine is usually

prescribed in a watery solution, while the combination of homatropine and paredrine is prescribed in a more favorable menstruum conducing to its greater concentration in the aqueous chamber and thus enhancing its effect.

Dr. J. I. Pascal agreed with Dr. Tassman in his insistence on accuracy and exactness in astigmatic corrections, provided the physiologic nature of the problem is not forgotten. In dealing with a living dynamic organ the degree of mathematical exactness must be commensurate with physiologic variations. Even if the astigmatism is corrected with theoretical precision, there are still intrinsic variabilities in the astigmatic correction which cannot be eliminated.

Dr. Tassman concluded by stating that paredrine is effective as a cycloplegic only when employed with homatropine and atropine, and does enhance their value. Paredrine is not of itself a cycloplegic and even homatropine has been said at times to be unsatisfactory when used alone. The innervation of the ciliary muscle is a large subject and one which is still discussed.

The refractionist should try to obtain a mental picture of the patient's condition, particularly with reference to the accommodation. There are, of course, several different ways of measuring the accommodation; this should be satisfactorily estimated and, if residual accommodation remains, its extent should be known and taken into consideration. There should be an attempt to determine the extent to which the symptoms are caused by the astigmatism present, by the activity of the accommodation, and the occupation of the patient. These three factors together with the age must all be considered in order to prescribe a correction which will provide the relief that the patient seeks.

USE OF MYODISC LENSES IN THE POST-OPERATIVE TREATMENT OF RETINAL DETACHMENT

DR. ERNST L. METZGER stated that the Lindner pinhole spectacle with its 3-to-5-mm. peephole results in a very limited visual field. The return of a patient who has been operated on for detachment to normal life is facilitated if, after he has worn the stenopeic spectacles, myodisc lenses with the smallest diameter available are used. They are less conspicuous than the stenopeic spectacles and prevent excess rotation of the eyes for a much longer period after the operation. The patient is more willing to wear them; some patients, in fact, do not return to the use of the usual lens at any time. To be effective, there should be a difference of from 6 to 10 diopters between the central corrected portion of the lens and the peripheral flat part. A hook-on addition is prescribed for the presbyopic patient.

January 15, 1945

DR. SAMUEL J. MEYER, *president*

FIRST ANNUAL SANFORD R. GIFFORD
MEMORIAL LECTURE

THE PATHOLOGIC PHYSIOLOGY OF CON-
VERGENT STRABISMUS

DR. FRANCIS HEED ADLER presented a
paper on this subject.

CLINICAL MEETING

(Given by the Department of Ophthal-
mology, Northwestern University)

CENTRAL MYOPIC DEGENERATION OR CEN-
TRAL RETINAL VASCULAR DISEASE

DR. HELEN HOLT said that Mrs. B. H.,

aged 50 years, had experienced sudden loss of vision in the right eye on November 23, 1944. No general symptoms were associated nor was there ocular pain. On December 14, 1944, when seen in the Clinic, the corrected vision was R.E. 10/200; L.E. 20/70. In 1941, with the same correction (R.E. -2.25D. sph. \approx +1.00D. cyl. ax. 155°; L.E. -12.00D. sph. \approx +2.00D. cyl. ax. 75°) the vision was R.E. 20/25-3, L.E. 20/40. At that time the right eye was normal and the left had a posterior staphyloma, myopic degeneration, chorioretinitis, and a stellate cataract on the surfaces of the adult nucleus.

On examination there was found a large retinal and preretinal hemorrhage in the macula of the right eye. During the following weeks this gradually cleared, leaving a gray elevated area in the macula, about 2 to 3 disc diameters in size, surrounded by a crescent-shaped hemorrhage. All tests for foci of infection were negative. Peripheral arteries showed Grade-II angiospasm. Chorioretinitis was ruled out, and the differential diagnosis between myopic central degeneration and central retinal angiospasm was considered. Since the changes occurred in the eye with the mild myopia, the first etiology seemed less likely. The elevation of the lesion with edema and peripheral angiospasm led to the choice of central retinal angiospasm or vascular disease as the etiology. Treatment with depromanex was continued, but the vision did not improve beyond 20/200.

POSSIBLE PARTIAL CLOSURE OF THE CENTRAL ARTERY

DR. HELEN HOLT said that Mr. P. P., aged 60 years, had been treated in the medical clinics for mild arteriosclerosis obliterans from August, 1944, until December 6, 1944, at which time he was ad-

mitted to the Eye Clinic. Twenty-four hours previously, while sitting, the vision of the left eye blotted out. There were no associated symptoms. Visual acuity was R.E. 20/25, L.E. 10/200. Blood pressure was 160/92.

External examination revealed no abnormalities, and both fundi appeared normal except for questionable narrowing of the arteries. Fields showed a 20- to 40-degree central scotoma in the left eye. Vasodilators, papaverine by mouth, and intravenous typhoid vaccine were administered, with no improvement in visual acuity or fields. On January 9th, very slight pallor of the disc of the left eye was observed, and a slight enlargement in the central scotoma was elicited. A diagnosis of partial occlusion of the central retinal artery of the left eye in an individual with early Group-I arteriosclerotic retinopathy was made.

DEEP TUBERCULOUS KERATITIS TREATED WITH BETA EMANATION

DR. HELEN HOLT said that Mrs. D. McQ., aged 31 years, suddenly complained of a foreign-body sensation in the right eye during a routine eye examination on September 30, 1944. No pathologic change was found. She returned on October 18th, when the eye was slightly injected and there was considerable photophobia. Corrected visual acuity had dropped from 20/25 to 20/40. Ciliary injection was present on the nasal side of the cornea and gray infiltrates extended into the cornea from the limbus for a distance of 2 mm. on this side. Folds in Descemet's membrane were numerous, but no vessels were present. A diagnosis of deep keratitis was made.

Wassermann and Kahn tests had been negative prior to two pregnancies; the last cesarean section was performed about 15 weeks prior to the onset of the eye symptoms. The tuberculin test was positive and

tuberculin therapy was instituted. Locally, atropine and heat were advised. The lesion progressed steadily until the entire cornea was gray, and all of Descemet's membrane was involved. The cornea remained avascular except for one deep vessel at the 3-o'clock position, extending in about 2 mm. Vision was reduced to perception of hand movements. On October 23d an X-ray treatment was given, and beta-emanation therapy on October 30th, November 6th and 27th. On November 21st definite improvement was noted, and the infiltrates gradually faded from the periphery inward. On January 8th only a small gray area above the center of the cornea remained, and the corrected visual acuity had returned to 20/25.

TUBERCULOUS KERATITIS

DR. BEULAH CUSHMAN presented Mrs. A. S., aged 34 years, who had been under antisyphilitic therapy. On September 16, 1944, she was referred for an eye examination because of pain and photophobia in the left eye. Vision was 20/50, corrected. A corneal ulcer was found superimposed on an old corneal scar which had been presumed to be interstitial keratitis. In spite of treatment with atropine, vitamins, and cauterization the area continued to break down, and fresh infiltrates persisted beneath Bowman's membrane. On October 13, 1944, a positive skin reaction to purified protein derivative was obtained and tuberculin therapy was instituted. This was continued, with gradual healing of the lesion. Ciliary injection and corneal vascularization disappeared and a gray nebular scar occupying the upper central portion of the cornea remained. The corrected visual acuity was 20/50+3.

Robert Von der Heydt.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

January 18, 1945

DR. WARREN S. REESE, *chairman*

ACQUIRED PTOSIS, CLASSIFICATION AND CORRECTION

DR. EDMUND B. SPAETH presented an analysis of over 200 patients in whom an acquired ptosis was either the sole complaint, or ptosis appeared as a part of the symptom complex of the underlying condition. From these cases a classification was developed based upon anatomic and etiologic characteristics. Instances of each subdivision were shown with lantern slides.

The varied surgical means for correcting these different conditions were presented. All forms of symptomatic ptosis are not surgical conditions. Those, however, which are such, need individual attention depending upon the underlying characteristics of the case under consideration. (See this Journal, October, 1945.)

Discussion. Dr. James S. Shipman said that Dr. Spaeth had shown a great number of cases of ptosis that many never thought occurred. Usually ptosis is considered a congenital condition which can be corrected by one of many different operations, and the reason that there are so many different operations for ptosis is that none of them are perfect.

Dr. Spaeth demonstrated that ptosis does occur after birth, due to many causes, and is not by any means always congenital. Before operating on any patient with ptosis, one should first determine whether or not the condition is congenital in origin. If it is a case of acquired ptosis, what is the reason for it? What is the pathology? Unless this investigation is made, difficulties may arise

that otherwise could be avoided. Certainly in ptosis due to syphilis or myasthenia gravis, one does not wish to try operative intervention. There are many pitfalls that one is liable to fall into by being too quick to operate for ptosis. Make sure first of the diagnosis as to the reason for ptosis, and, when that is decided, then with due consultation, plan a procedure that will relieve the ptosis. As Dr. Spaeth showed, the operative principle used in correcting acquired ptosis is very much the same as that used in correcting congenital ptosis. The cause, the scar tissue, and the pathologic change present, however, modify a great deal the technique that is to be followed.

Included in the cases presented by Dr. Spaeth were some which Dr. Shipman had referred to him. He particularly wished to mention the case of the woman who had a pachydermatocele. There was an enlarged eyelid that hung down on her cheek, and the eye protruded out to the cheek also. He said she had one of the worst looking eyes he had ever seen. When last examined she had a good socket, and a well-fitted artificial eye. He said he had assisted Dr. Spaeth in one stage of the operation in which the dura was uncovered in the roof of the orbit. This was a very difficult case to follow through, requiring a great deal of patience and skill, and more than the average amount of boldness to bring this woman's face to a normal appearance.

REVIEW CONCERNING ABERRATIONS OF THE EYE

DR. ALFRED COWAN said that Thomas Young, as early as 1801, showed conclusively that the eye was neither achromatic nor aplanatic. Many others, particularly Volkman, Donders, J. H. Knapp, and Tscherning, investigated the aberrations of the eye; but the most thorough study of the actual image of the eye was made

by Gullstrand. He found that the caustic surface is extremely intricate, and that it varies as the meridian section is revolved around the axis.

In the eye there are not only all the aberrations which must be eliminated in a well-designed artificial optical instrument, but the added faults that exist in a living asymmetric organ.

The aberrations of the eye are physiologic, and their absence would be of no use for the eye. The effect of the circle of least confusion is that of a point image as long as its diameter does not exceed the revolving power of the eye. The retina is sensitive to distinct visual acuity only in a very small area at the fovea, and for this reason only that part of the caustic which is found most useful is utilized. The surrounding halo is disregarded. Also, because of the peculiar structure of the retina, the effects of marginal astigmatism, curvature of field, distortion, and so forth, are negligible. The faults of the optic system of the eye do not interfere with distinct visual acuity.

Discussion. Dr. Francis Heed Adler said that this paper indicated fair-mindedness in at least one physiologic optician. The majority seem to have such faith in geometric optics that they are like an economist who willfully blinds himself to the frailties of human nature in order to believe wholeheartedly in the doctrines of Karl Marx. They insist on speaking of point image on the retina, although they know they do not exist. This has seriously retarded the knowledge of visual physiology, and Dr. Lancaster is quite right in emphasizing the importance of learning about image formation in the eye as it occurs in nature, and not as it is pictured in geometric optics. He agreed with Dr. Cowan that geometric optics should be taught as the basis for physiologic optics, but the student must be carried beyond this, and instructed in image formation

as it actually occurs in the human eye.

Dr. I. S. Tassman commended Dr. Cowan for pointing out the benefit of retinoscopy in at least obtaining an approximate determination of the refractive state.

It seemed to him that in recent years there had been a tendency to, perhaps, overemphasize subjective examination in refraction, or at least to emphasize certain subjective tests and methods for determining the result in refraction. At the same time, in a great many instances, the objective examination is neglected. He said that a paper of this kind would help to overcome some of the objections that have been advanced about objective examination and retinoscopy, particularly in those cases in which cycloplegics are employed. One of the chief objections to the use of cycloplegics has been said to be the very large pupil, and the difficulty in making a retinoscopic examination of the central area.

This, as Dr. Cowan pointed out, should not present any difficulty to one with any experience at all in retinoscopy. He said that he would add that retinoscopy should be performed in every case preliminary to subjective examination regardless of whether a cycloplegic has been employed or not. He said it is a mistake in the examination of the presbyopic especially, to omit retinoscopy.

INFECTION OF THE HUMAN EYE WITH TORULA HISTOLYTICA

DR. CHARLES WEISS, DR. M. C. SHEV-
KY, and DR. I. H. PERRY said that through the coöperation of Dr. Martin I. Cohen of San Francisco, they examined material obtained by trephining the sclera of a patient in whom the clinical diagnosis of a possible cyst of the retina had been made. The following history was given:

Mr. A., aged 56 years, had been in an automobile accident in 1941. In July,

1943, Dr. Nutting of Oakland, California, discovered a growth in his right eye, and enucleated the eye in October, 1943. Three months later the patient complained of poor vision in the left eye. He soon developed mental symptoms, and was confined in a sanitarium. The eye showed fine deposits on the posterior surface of the cornea, and on the anterior surface of the lens. There were "floaters" in the aqueous and vitreous. A diagnosis was made of "possible cyst of the retina with retinal detachment and uveitis." The sclera was trephined, and material obtained for culture showed the presence of a yeastlike organism which was identified as *Torula histolytica* (*Cryptococcus hominis*). This was the second case in the literature of an ocular infection due to *Torula histolytica*.

In its cultural characteristics the organism resembled Benham and Hopkins's *Torula* Group III when grown in cornmeal agar. Its ability to ferment carbohydrates was weak and variable. No gas was formed. Gelatin was not liquefied. There was abundant budding, but neither mycelia nor endospores were formed. The organism killed mice when injected intraperitoneally or intravenously.

When the culture was injected into the anterior chamber of the eyes of rabbits, it was possible to observe very early pathologic changes. The inferior part of the anterior chamber became opaque, and a pannus developed on the surface of the cornea.

Histologically there was a slight exudate consisting of polymorphonuclears and some monocytes along the periphery of the cornea. Along the anterior surface of the iris and the posterior surface of the cornea, there was a delicate festoon of rosettes. In the center of each rosette, there was a *Torula* organism surrounded by a single row of cells (polymorphonuclears and monocytes). *Torula* were seen engulfed within macrophages.

Discussion. Dr. William O. LaMotte, Jr., said that this organism known as *Torula histolytica* was brought to the attention of the Eye Department of the University Hospital during the past year through the opportunity of observing the eyegrounds of a patient on the Orthopedic Pediatric services who subsequently died of a *Torula histolytic* infection of such widespread degree that the term torulosis could aptly be applied to it. A report of this case will be published by Dr. Joseph Snyder, the resident pathologist at the University Hospital. This six-year-old girl was originally admitted for penicillin therapy of a chronic osteomyelitis in the left femur and right humerus. The offending organism was hemolytic *Staphylococcus aureus*. It was not long after admission that signs of a generalized systemic infection and involvement of the central nervous system appeared, including an increase in the cerebrospinal-fluid pressure. Many *Torula* organisms were isolated from the spinal fluid both by direct smear and culture. Despite massive doses of penicillin, intramuscularly and intrathecally, the child died. The penicillin therapy did not influence the number of organisms found in the spinal fluid. It was about six weeks after the first sign of the central nervous involvement that the child died. During all this time, she was kept under observation so far as the fundus was concerned. There were no definite changes until a week before death, at which time a bilateral papilledema of 2 to 3 diopters appeared. Also, in the region of the posterior pole of each eye, there were seen a number of poorly defined, pale yellow areas about one-eighth disc diameter in size, and deep to the retinal vessels, having somewhat the appearance of deep necrosis or deep exudates.

At the autopsy the orbits were unroofed, and the posterior segments of the

eyes were removed. In view of the fact that this *Torula* organism was found histologically in practically every tissue of the body, it was thought that perhaps the finding of *Torula* might explain these patches that were observed ophthalmoscopically in the eye before death. Sections did show in the retina a few nests of *Torula histolytica*, although not in so great abundance as was expected, judging from the lesions seen ophthalmoscopically.

This case, and the subject of *Torula*, brings up several interesting points. One is the fact that some authorities, and it is believed that Dr. W. Freeman and Dr. Fred Weidman are probably the principal ones, believe that the term *histolytica* is a misnomer, and in their experiments have shown that the organism is not actually histolytic for nervous tissue. Some of the brain sections from this case showed typical cystic areas containing *Torula* surrounded by brain tissue which had a compressed appearance. This in a sense might uphold the thought that the typical appearance is due to a disruptive rather than to a destructive process from the actual growth of the organism.

The portal of entry has always been a problem, and it has not been solved in this nor any other case. In this particular case, one would naturally expect that it might be the draining sinuses in the infected bones. However, at no time was anything

but hemolytic *Staphylococcus aureus* obtained by culture from these lesions, although *Torula* were found in abundance histologically in the bone marrow as elsewhere.

Another point is that in all the articles that have appeared, and also in the recent one by Dr. Martin Cohen (*Archives of Ophthalmology*, December, 1944), the statement is made that this organism, genus *Torula*, occurs widespread in nature. He said he understood from Dr. Weidman, however, that an organism which can produce infection in the human or in an animal has not been found in nature; that these organisms of this group found widespread are all saprophytic, and that he considered it still a problem as to where this particular organism that causes human infection resides in between these relatively infrequently reported cases. He asked if, in his experiments, Dr. Weiss had used only the organism isolated from his case, or if he had actually attempted to produce animal infection with some of these organisms which had been found from this widespread source in nature.

Dr. Charles Weiss, in reply, said that only the strain which was isolated from the patient was used to produce the lesions in the rabbit's eye.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to *Dr. Donald J. Lyle*, 904 Carew Tower, Cincinnati, 2, Ohio. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 837 Carew Tower, Cincinnati, 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

PROBLEMS OF POSTWAR OPHTHALMALOGIC TRAINING

It is unfortunate that so many good ophthalmologists were not used to better advantage in the Armed Forces. To some extent this was unavoidable, since the age group of the service personnel largely excluded glaucoma, senile cataract, and the degenerative diseases. This fact, together with the mass of paper work, the annoying details of maintaining military discipline, or the enforced periods of com-

plete inactivity, has made the average ophthalmologist feel that his time in the Army or Navy was more or less wasted, as far as scientific medicine was concerned. There are exceptions, of course, but a large proportion of them now returning to civilian life feel this way. These men have a sense of insecurity about reëntering the competition of private practice, and more and more of them are demanding refresher courses. It seems only right that their desires should be gratified.

In addition to this, many young medical officers who were denied the opportunity of taking a residency in ophthalmology, now wish to begin one. Based on replies received to questionnaires, the council on Postwar Medical Service of the A.M.A. has recommended that every approved ophthalmologic residency in the country increase the number of its house officers by 90 percent to accommodate this demand!

We are therefore faced with a problem of "reconversion" in ophthalmic education quite as serious as that which confronts industry.

In the editorial columns of the September, 1945, issue of this Journal, Post pointed out the need for every medical school and hospital to stretch its facilities to the utmost to provide places for these homecoming physicians. To take care of all of them would put too much strain on the already depleted facilities of these institutions and so impair the quality of the teaching that the expected benefits would not be realized. Every teaching center must, therefore, do the best it can in view of its resources and capabilities, keeping in mind that it is better to give good teaching to a few than poor teaching to many.

To help meet the demand for short periods of refresher work the Department of Ophthalmology of Harvard Medical School is planning to give two postgraduate courses early in 1946. The first course will last two months and will be devoted entirely to the fundamental sciences in ophthalmology. The subjects covered will be anatomy, histology, and embryology of the eye, bacteriology, physiology, pharmacology, and toxicology of the eye, neurology of the visual and ocular-motor pathways, and physiologic optics. Laboratory and experimental work will be included to illustrate the didactic exercises. This course is designed pri-

marily for young doctors who wish to enter ophthalmology as a preliminary to beginning their residency. It is hoped that it will also prove beneficial to older ophthalmologists who feel the need for review and reorientation.

This course will be followed immediately by a one-month course in clinical ophthalmology. In this, all aspects of the clinical and pathologic work at the Massachusetts Eye and Ear Infirmary will be dealt with, and the recent advances emphasized. This latter course is open only to ophthalmologists who have had a recognized ophthalmic residency and to other physicians who have completed the first course in the fundamental sciences, or its equivalent elsewhere.

A maximum of 30 veterans can be accommodated in each course. The major part of the tuition will be borne by the government under the G.I. Bill of Rights.

The above is illustrative of a short period of training. Other medical schools are planning to give longer courses of six to nine months for those veterans who desire them.

In regard to the feasibility of increasing the number of residencies, certain difficulties arise. Although the financial responsibility of the government is clear in regard to organized postgraduate courses conducted by a paid faculty in an established medical school, there has been no definition of policy concerning residencies for which no tuition fee is charged. The cost of maintaining a house officer (room, board, and laundry) amounts to about \$500 a year in the larger institutions. The addition of five or six extra residents for a two-year period would represent an added expense that many institutions might not care to assume. So far, this writer has not been able to obtain assurances from the Veterans Bureau that this maintenance charge will be paid by the government.

In fact, present instructions from Washington definitely state that payment for board, lodging, or other living expenses is prohibited. However, the Veterans Administration will pay to the veteran himself the usual \$50 a month (\$75 in case of a married man) for subsistence during his residency. There is some reason to believe that these amounts will be increased in the near future. Extra residencies must be created even though the housing problem in some hospitals may necessitate the veteran's living outside and paying for his own room. Such arrangements may seem niggardly in view of the sacrifices most of these men have made, but the housing situation may prove to be a formidable one if any substantial increase of residents is attempted.

Each institution will have to work out its own problem. It is hoped that each will do its utmost to help train these returning medical officers. The type of ophthalmologic care the American public is going to receive during the next 10 years depends, to a large extent, upon our willingness to participate in this training program.

Edwin B. Dunphy.

THE LOS ANGELES MID-WINTER POSTGRADUATE COURSE

The fifteenth annual mid-winter postgraduate course of the Los Angeles Research Study Club was held from January 21st to February 1st, inclusive. It has been the endeavor of those in charge to make the course essentially practical; to have "ideas presented that may be taken home to be utilized in everyday practice" and to stimulate the interest in "research study." This year the first week was devoted to the eye. Over 300 registered for the ophthalmologic portion of the course; in this registration 27 states and British Columbia were represented.

Dr. Alan C. Woods of the Wilmer Institute discussed the various phases of ocular tuberculosis; management, diagnosis, and treatment of uveitis; sarcoid; Brucellosis; the ocular complications of congenital and acquired syphilis; sympathetic ophthalmia, and the role of focal infection. Dr. Jack S. Guyton, also of the Wilmer Institute, discussed the various operative procedures used in ophthalmology together with a new operation for orbital decompression. Dr. Meyer Wiener presented the Naval ophthalmic problem and gave an instruction course on major surgical procedures. Diagnosis and differential diagnostic problems of glaucoma, congenital cataracts, and ocular therapeutics were discussed by Dr. Frederick C. Cordes of San Francisco. Irving B. Lueck of Rochester, New York, presented various aspects of physiologic optics together with a discussion of color aptitudes and the new antireflection coating of ophthalmic lenses. In addition there was a discussion of the everyday spectacle problems. From the titles mentioned it is apparent that the program was varied and essentially practical.

It is noteworthy that in spite of the hardships, difficulties, and limitations placed upon it the course was able to continue its annual meetings during the war and to contribute to the war effort by making it possible for the busy and often overworked civilian ophthalmologist to keep abreast of the newer developments during that trying time.

While many of those registered attended the course last year, it was apparent that this year a high percentage were newly discharged veterans or men still in the service. For many it was the first real contact with civilian ophthalmology for a number of years; they had, in some instances, been stationed in areas or on posts where there was little or no ophthalmology, while others were in execu-

tive positions where there was no contact with clinical medicine. The attentive attendance at the lectures from 9:00 in the morning until 5:30 in the afternoon and the interest in the informal discussions over a cocktail or a glass of beer at the end of the day further showed the desire of this group to utilize every opportunity of refreshing their knowledge of the specialty. The experience in Los Angeles tends to emphasize the responsibility of American ophthalmology to make available to the returning veteran the opportunity of renewing his acquaintance with clinical ophthalmology.

The officers of the Research Study Club who were responsible for the arrangements for the course and who "warmly welcomed as guests of the Club" those in the military service are to be commended for making available to many returning service men the very interesting and practical one-week course in ophthalmology.

Frederick C. Cordes.

THE CHALLENGE

It is possible that historical research would show that after every major war the victors have won, in addition to other things, the leadership in science, including medicine. To support this premise by a thorough study would be interesting but somewhat beside the point, for, whether we like it or not, the responsibility for leadership in the medical education of the world is one that is now placed on the shoulders of the United Nations, particularly North America, England, and possibly Russia. Europe is too devastated and debauched to stage a comeback for a good many years. Her influence as a center for medical and, what particularly concerns us, ophthalmic education began to wane following the last war. This is shown by a declining trend in the num-

ber of our postgraduate students, during the last two decades, who went abroad for the study of ophthalmology. In addition to the declining number, the quality of the students was obviously poorer than before World War I.

The interwar period in the United States was one of exciting progress in the evolution of medical education and postgraduate training. The results reflected by this magnificent training were revealed in the fine work done by our young medical officers and in the extraordinary statistics of the treatment of battle casualties in this war. Modern therapeutics played their part, but the credit truly belongs to the work of the civilian doctor in uniform for his superb professional care of the sick and wounded.

The influence that our Army and Navy hospitals, especially the "affiliated" units, have had by their impact on foreign physicians and surgeons everywhere in the world will begin to become manifest in the near future. The result will be an ever increasing number of observers, students, and medical missions from everywhere coming to our country and to our schools and hospitals to learn from us.

The mental and physical distress, during the war years and immediately thereafter, endured by Great Britain and suffered by the occupied countries has had and will continue for some time to have an unfavorable effect upon the development or expansion of their physical plants and facilities for medical education, as well as on the teachers themselves in those countries. The dogged leaders of British ophthalmology, however, were making splendid plans for the future of ophthalmic education and training even while flying bombs were exploding and air-raid sirens were wailing. These plans have made good headway, and it may not be long before various postgraduate

courses, long and short, are offered to the world. The situation in the defeated countries must be one of great pessimism. One does not know and at this stage scarcely cares to find out what happened to the leaders in ophthalmology in those countries. What little we have learned of the medical practice under Hitler, and the results as seen in the German military hospitals and in their terrible concentration camps, leads us to fear no rivalry from that detested source for a long time to come. Through no fault of ours, we know actually very little about Russian medicine and surgery. There is no doubt about the upsurge and vitality of medical science in Russia at the moment. The need for medical treatment brought on by and during the war has given an enormous impetus to the movement of earnest scientific education in that country. The position that the medical citizen under Stalin occupies is one of the highest prestige, and Russian ophthalmologists are in a particularly favorable light. The number and value of their scientific contributions are steadily increasing and becoming robust. It is exhilarating to watch their development. But their time will be too occupied and their facilities too limited to care additionally for the training of foreign postgraduate students in medicine, even if the latter were to be given free access into the country.

Thinking along these lines leads us to wonder whether we in the United States are prepared for and agreeable to the position of leadership in ophthalmic education. At the moment our facilities, too, are not enough to care for all of our own ex-medical officers who are looking for training in ophthalmology. There are too few ophthalmic residencies for one thing, and, for another, pathetically few medical schools are developing courses in basic ophthalmology. The pressure of the demand for such courses is becoming nearly

too great to bear, and more schools will be forced into giving them.

It is admittedly difficult for most medical schools to initiate and carry out basic and other courses in ophthalmology. This is partly because the ophthalmic staffs of many of the schools are essentially made up of voluntary clinicians who can spare but little time from their practices for the care of clinic patients, let alone teaching. It is also due to the rather low estate in which ophthalmologists are held by their fellows in general medicine and surgery, particularly on the faculties. This low opinion is a fact that was emphasized by Army experience. The attitude may be the result in part of the aloofness or clannishness or even inertia of the ophthalmologists themselves, but is probably the consequence of poor courses and propaganda in ophthalmology given to our general medical colleagues when they were medical students. Frankly, most of us have been too busy to teach our subject properly and with enthusiasm to the undergraduates. It may be necessary to "sell" ophthalmology to some of our medical schools in order to get necessary help in creating basic and even clinic courses. The Army or Navy ophthalmologist has done an excellent job of "selling" his specialty to his chief. Many of the latter have learned to hold in highest esteem the work of his ophthalmic medical officer and his place in the surgical specialties. At any rate, most of the chiefs of the surgical services in our Army hospitals have learned the difference between an optometrist and an ophthalmologist, which difference few of them knew or cared to know before the recent experience.

There is always the problem of sufficient financial backing for these undertakings. The fees for the courses probably will not cover the expenses. Equipment is difficult to find now and physical

things, such as suitable laboratory space and material and a lecture room, may be sadly lacking. More full-time or part-time teachers of ophthalmology must be provided for. Enough money must be raised for the eye departments of all our schools to develop and carry on the work of undergraduate and postgraduate teaching. There are 59 Class A medical schools in our country today and not more than six at the moment are giving or planning to give basic courses in ophthalmology.

We will have the backing of our ophthalmic associations and presumably that of the national medical societies as well in this venture. We will have the grateful support of the American Board of Ophthalmology, which is struggling with the problem of raising standards at a time of inadequate equipment for training and in the face of an overwhelming demand for such training.

Have we the energy, vitality, and initiative to accept the challenge and to seize the opportunity?

Derrick Vail.

BOOK NOTICES

THE FUNDAMENTAL COLOUR SENSATIONS IN MAN'S COLOUR SENSE. By Gustaf F. Göthlin. Seventy pages, 21 illustrations. Stockholm, Almqvist-Wiksell, 1943.

This summary in English of Göthlin's experimental results and theoretical views as to color vision marks a return of the author to this field of activity after a 20-year preoccupation with other subjects. The theoretical views are based upon the particular three-components formulation generated by choosing as fundamental colors red, green, and blue. Red plus green cancels to yellow, and yellow plus blue cancels to white. In these respects, Göthlin's views agree strikingly

with those put forward by Ladd-Franklin in 1892, which, surprisingly enough, are not mentioned by him. The mechanism by which red-green and yellow-blue cancellations are accomplished, however, is taken to be an inhibitory action in the central nervous system. These views are adequate to account for Göthlin's experimental results on energy thresholds for the red sensation, on the situation and extent of the purely yellow zone in the spectrum of anomalous trichromats; and on energy thresholds for the blue and violet sensations; and like the Ladd-Franklin theory they account for a large proportion of the known facts of vision. They have not, however, been developed very far beyond the qualitative stage and in some respects seem rather confused.

For example, Göthlin rejects the urge of previous advocates of the three-components theory to choose imaginary colors for primaries, thereby eliminating negative portions of the three spectral curves of trichromatic coefficients. He says (p. 60), ". . . these (negative portions) really mean that an impulse for a colour sensation of whatever quality releases to some extent an inhibition of impulses for the complementary colour sensation within the same area." Such a view implies that the spectrum primaries, to which the coefficient curves refer, can correspond to the fundamental colors, themselves; but it is also stated (p. 68) that "no isolated fundamental colour sensation can be experienced subjectively—with the *possible* exception that the most long-wave red in a completely pure spectrum may give such a sensation of red. . . ." The difficulty is treated most elegantly by G. E. Müller (*Z. Psychol.*, 1930, v. 17).

In spite of difficulties not resolved, and in spite of space wasted in summarizing inconclusive support for views already better supported by other work, there is

much in this summary to interest a student of visual theory. For example, the variations among different subjects with normal color vision in the position of the spectral zone for pure yellow are plausibly accounted for by supposing the existence of an individually varying proportion of the number of receptors for red and for green combined with a mass action giving more weight to the central impression of a fundamental color component when the number of its excited receptors is greater. Furthermore the perception by a congenitally yellow-blue-blind observer (the famous case of Alrutz) of the short-wave end of the spectrum as "red with black spots" may be explained in the same way. Even the highly elaborated theory of Müller does not seem to do quite as well on these points.

D. B. Judd.

GENERAL AND PLASTIC SURGERY. By J. Eastman Sheehan, M.D. 1st Edition, clothbound, 345 pages, 495 illustrations. New York and London, Paul B. Hoeber, Inc., 1945. Price \$6.75.

This book, which is the fifth in the career of the author, is not primarily a text for ophthalmologists but rather a treatise on general surgical techniques with an emphasis on war injuries.

The first four chapters deal with the agents which produce war wounds, the nature of such wounds, wound excision, and the control of wound infection. The author points out that prior to World War II, reliance was placed chiefly on bactericidal action, but after the power of the sulfonamides to induce bacteriostasis was demonstrated, attention has centered on this later method. Some space is devoted to the use of sulfonamides and penicillin. Chapter five deals with the subject of burns and their treatment. It is

encouraging to note that he recommends that the tannic-acid treatment be abandoned and the wound be treated as an open wound with special attention to the elimination of infection and replacement of lost skin as early as possible. The major portion of the text is devoted to the care of wounds, and an attempt has been made to cover the whole field of surgery. The section on wounds of the face includes wounds of the orbit, and the discussion on reparative procedures about the eyes is brief and incomplete. The chapter on tissue replacement demonstrates the different types of skin flaps and classifies skin grafts on the basis of their thickness. Some attention is devoted to the Padgett dermatome, and there is a discussion of plasma and white-cell fixation of grafts and the use of other materials for plastic repair. The last two chapters are devoted to the healing of wounds and elaboration on the details of surgery for repair of the nose, the mouth, facial contours, the eye, and the ear.

The illustrations, which are numerous, consist chiefly of line drawings, and there is a tendency to oversimplification.

The book is interesting and contains much informative material but it is not comprehensive enough to be classified as a complete reference book on modern operative methods. No one can be experienced and well informed in the whole field of surgery, and, in our present day of specialization, the need is for books which cover a small field thoroughly rather than those which cover the whole field inadequately.

Irving Puntenney.

CORRESPONDENCE

PRESBYOPIA ASSOCIATED WITH
ALTERNATING SQUINT

Editor,

American Journal of Ophthalmology:

I have been unable to find in the literature or texts any mention of the advantage to which alternating squint may be put in connection with prescribing lenses for the presbyopic. Nevertheless, a presbyopic patient with alternating squint can be made comfortable for both distance and near vision without the use of bifocals. I presume that others may have used the same means as I to accomplish this, for the method is simple and the results are greatly superior to those obtained with conventional glasses. However, if my method has been used before, no ophthalmologist appears to have taken the trouble to publish it, nor has it been mentioned in any textbook on refraction.

The method is simply to supply a distance lens for one eye and a near lens for the other. With a little patience and demonstration with the trial frame the patient readily learns how to use such glasses. If he is sufficiently presbyopic to need a +2.50 D.sph. addition, he can be given a distance lens for one eye and a bifocal for the other. The upper part of the bifocal would contain an addition of +1.25 D.sph. and the lower part an addition of +2.50 D.sph., the segments set high—up to the lower edge of the pupil. Thus he obtains the equivalent of a trifocal without being subjected to the inconveniences his neighbors have with their bifocals!

Care must be taken to differentiate between occasional squint and true alternating squint; for if a patient with the former type of strabismus is supplied with

these glasses, he will probably complain of diplopia or blurring. However, I have one patient who has an occasional squint with an exophoria of 30D. and who so disliked his bifocals that, in desperation, I suggested he try the method I have just outlined. He managed successfully to suppress vision in the non-used eye and went happily about his work with an alternating extropia which gradually grew to 50D.

Should the strabismic patient see well with both eyes but nevertheless use one eye almost exclusively, it might be advantageous to prescribe a bifocal for the dominant eye and a distance lens for the less-used eye. The patient can then use the dominant eye for both near and distance, but can switch to the other eye when going downstairs, walking over rough ground, and at other times when he requires good vision for distant objects below the level of his bifocal segment.

If one does, routinely, the simple muscle tests that are necessary to obtain a good eye examination, one will discover quite a number of presbyopic patients with alternating squint.

I do not know of any more grateful patients than these. All their lives they have considered their eyes inferior to the eyes of their neighbors. Now, finally, they can be told that the opposite is true—they belong to a very exclusive group of people who will never need to wear bifocals!

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |

I

GENERAL METHODS OF DIAGNOSIS

Baltin, M. M. Falta's test in diagnosis of monocular blindness or marked reduction of vision or their simulation. *Viestnik Oft.*, 1944, v. 23, pt. 4, p. 22.

The best method for detecting simulation of monocular blindness should involve no special apparatus, should be quick, and should be capable of convincing lay persons. Falta's test consists in the patient fixing the examiner's finger at six inches from the nose and 1 cm. from the midline in the direction of the affected eye. Normally this is within the range of the near point of convergence. The finger is then brought closer and closer to the nose. A blind eye or an eye with marked reduction of visual acuity begins to turn out as the finger comes closer. In the presence of hyperopia or presbyopia +2 or 3D. lens is used in performing the test. M. Davidson.

Buerki, E. and Schmid, A. E. Histochemical investigations of the demon-

stration and localization of vitamin C in the eye. *Ophthalmologica*, 1943, v. 105, Feb., March, April, pp. 65-82 and 121-143.

The authors investigated various eye tissues for the presence of ascorbinic acid. Tissues of the eyes of normal and of scorbutic guinea pigs were placed in an acid silver-nitrate solution. Tissues containing vitamin C reduce this solution and show black granulated deposits within their cells. The eyes of normal guinea pigs showed reduction granules in the cells of the parenchyma and the epithelium of the cornea, the stroma of the sclera, the pigment epithelium of the iris, the stroma of the ciliary body, the choriocapillary layer of the choroid, the multipolar ganglion-cell layer of the retina and within the lens fibers. The optic nerve is practically free from ascorbic acid. Eye tissues from guinea pigs suffering from scorbutus had no reduction granules. The significance of this histochemical investigation for the question of the metabolism and cell mechanism of the

tissues of the eye is stressed and discussed. (Bibliography).

Max Hirschfelder.

Hruby, K. Slitlamp microscopy of the fundus without contact glass. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 195-200.

To make the fundus visible in slit-lamp microscopy the angle between the axis of the lamp and of the microscope must be made very small, and an image of the fundus must be brought within the focal distance of the objective of the microscope. This has been done by means of a heavy, awkward, contact glass which cannot be used with children or nervous and sensitive adults. The reduction of the angle has been accomplished by Koeppe with a silver mirror and by Lindner with an angulated microscope. The Swiss firm Haag-Streit has replaced Koeppe's mirror with a prism which is very satisfactory. The author avoids the need for a contact glass by placing a 55D. concave spherical lens before the patient's eye in a spectacle frame. He recommends this as an adequate method, particularly to those who have a Haag-Streit slitlamp. Users of a Zeiss slitlamp will need a Lindner angulated monobjective microscope. (References.)

F. Herbert Haessler.

Koch, F. L. P. *Ophthalmodynamometry*. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 234-247.

Adequately to abstract this very complete review of considerable literature on ophthalmodynamometry is difficult. The author's own conclusions are as follows:

"It is unfortunate that the few studies which have been carried out in some detail with reference to the vari-

ous pressure relationships involved have not followed a relatively standard procedure with regard both to the ophthalmodynamometric methods and apparatus employed and to the classification of normal and of abnormal states according to uniform criteria of diagnosis. The reports in the available literature, however, with respect to investigations on the various vascular pressure relationships confront the worker in this field with an inescapable sense of the futility of efforts to arrive at any reasonably definite values for the normal retinal blood pressures. It becomes practically impossible, therefore, to rely diagnostically on the figures given by the various investigators for the retinal blood pressures in the numerous forms or stages of local and systemic hypertensive disease of whatever cause. It would appear to be much more reasonable to depend primarily on the information gained from a careful ophthalmologic examination, with particular reference to all of the changes that manifest themselves in the retinal vessels, particularly the arterioles, and in the retina and choroid as well, and these findings necessarily must be correlated with the results of the general physical examination."

R. W. Danielson.

Lathrop, G. E. *Microtechnique of pathologic eye*. *Amer. Jour. Clin. Path.*, 1944, v. 14, Nov., p. 131.

Tissue components of the eye are extremely variable. The succulent retina has to be fixed by a fluid which does not superimpose hardening on the toughness and friability of the cornea, the sclera, and the dural sheath of the optic nerve. For any purpose other than storage the pathologic eye should never be fixed in 10-percent formalin. Two for-

mulas are presented by the author for fixation. Dehydration must be accomplished with a minimum of shrinkage and distortion.

Theodore M. Shapira.

Niederhoffs, P., and Kemp, R. **Examination of the field of vision with a flicker perimeter.** *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 257-265.

The principle of this method has been described previously (*Amer. Jour. Ophth.*, 1936, v. 19, Oct., p. 912). In the meantime the apparatus has been somewhat modified. The visual stimulus produced by intermittently appearing and disappearing white and colored (pigment) lights is argued to give more accurate results in perimetry than other methods, not only for determining the limits of the peripheral visual field but also for evaluation of pathologic scotomas and the blind spot. In glaucomatous eyes, disappearance of the flicker phenomenon is observed where light perception for constant lights is still present. (3 figures, 2 tables.)

F. Nelson.

Scharf, Josef. **Demonstration of an intraocular foreign body by means of gonioscopy.** *Klin. M. f. Augenh.*, 1941, v. 107, Aug., pp 193-196. (See Section 16, Injuries.)

Shenkin, H. A., and Leopold, I. H. **Localizing value of temporal crescent defects in the visual fields.** *Arch. Neurol. and Psych.*, 1945, v. 54, Aug., p. 97.

These cases are presented to emphasize that careful perimetric studies may reveal a crescentic defect in the temporal portion of the visual field which is of practical importance to the neurologist and the neurosurgeon. A monocular crescent defect indicates the general

area involved by a tumor or other pathologic process.

In five cases presented here, unioocular temporal-crescent defects in the visual field were due to verified cerebral tumors involving the suprageniculate pathway. This finding is important as an early localizing sign.

Theodore M. Shapira.

Troncosco, M. U. **A new contact glass for gonioscopy.** *Amer. Jour. Ophth.*, 1945, v. 28, Dec., pp. 1360-1361.

Verrey, F. **An arrangement for capillary centrifugation.** *Ophthalmologica*, 1943, v. 105, March-April, pp. 151-155.

An arrangement is described whereby the centrifuged sediment from a capillary tube of aqueous may be placed on the cover glass. Smallest amounts of aqueous humor could be examined by this method from a cytologic and microbiologic standpoint.

Max Hirschfelder.

Vogt, Alfred. **Selected chapters from volume 3 of the author's Atlas of slit-lamp microscopy.** *Klin. M. f. Augenh.*, 1941, v. 107., Oct., pp. 435-442.

1. Vogt calls attention to the senile destruction of cells of the posterior pigmented epithelium of the iris and the deposition of their pigment in granules on the pupillary margin. Less well known is the pigment-cell destruction which occurs in the anterior mesodermic iris tissue during an attack of acute glaucoma and leaves a hitherto neglected picture, namely of areas of albinism or vitiligo of the iris. The pigment finds its way into the aqueous, and, being dense, is deposited in the dependent part of the chamber angle like blood cells in hyphema. Vogt suggests that this manifestation be called hypo-

melanosis. The peculiar lesion is often accompanied by changes in the lens cortex. These consist of branched opacities for the most part associated with the lenticular raphe. Unquestionably this cataract is produced in increased pressure which may be caused by glaucoma or a blow on the eye. In time the cataract sinks into the interior of the lens as new fibers grow over it.

2. Many observations, clinical and anatomic, lead the author to conclude that the hyaloid canal does indeed exist in the human vitreous and that its landmarks are gradually obliterated through a lifetime of stresses and strains produced in the vitreous by ocular movements. Hemorrhages sometimes delineate its anterior end, and are found 2 mm. nasal to the posterior pole of the lens. The postlental curvilinear white line which formerly was only of theoretic interest now has pathologic importance. Vogt also mentions that volume 3 of his Atlas contains many pictures which clarify posterior annular vitreous detachment.

F. Herbert Haessler.

THERAPEUTICS AND OPERATIONS

Aguirre, José. An essay of the real and comparative value of prontosil and albucid in the treatment of blennorrheal purulent conjunctivitis. *Rev. Oto-Neuro-Oft.*, 1944, v. 19, Oct., pp. 132-134.

The series treated consisted of 12 cases, eight of which occurred in children between 15 days and three years of age. The other four were in adults between twenty and forty years of age. The methods utilized were local instillation, injection, and peroral administration. All cases of this blennorrheal conjunctivitis improved with

treatment, and did equally well when using prontosil or albucid as a collyrium, or by injection. Albucid perorally yielded better clinical and bacteriologic results than prontosil.

Edward Saskin.

Amsler, M., and Verrey, F. The practical use of puncture of the anterior chamber. *Ophthalmologica*, 1943, v. 105, March-April, pp. 144-150.

Punctures of the anterior chamber for diagnostic reasons have been done in the Lausanne eye clinic on 1,065 eyes during the past two years. The puncture is made by a specially constructed needle. It is a harmless procedure and gives useful information as to the composition of the aqueous humor (albumin, cells) in different eye conditions. The reaction of the eye to the paracentesis with regard to exudation, tension, and resistance of the vessel is noted. Diagnostic puncture is of value in uveitis and other inflammatory conditions of the anterior part of the eye, in hypertension, in injuries, and before intraocular surgery.

Max Hirschfelder.

Arruga, H. Experimental and clinical studies with penicillin in ophthalmology. *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 847.

Arruga demonstrated experimentally the antibacterial action of penicillin, by producing experimental corneal ulcers and intraocular infections and using one eye as a control. Before using penicillin clinically he demonstrated on patients and on himself that even a concentrated solution or ointment of sodium penicillin is well tolerated by the eye, provided that the penicillin is pure. He reports four cases of serpiginous ulcer, three of which recovered; in the

fourth the result was an opaque leucoma. The action of penicillin in these cases is not so spectacular as it is in general infections, but the drug is the best antiseptic at our disposal. Injections into the lacrimal sac were tried in six cases of dacryocystitis. The supuration cleared up in 3 to 9 days. In three cases the remaining exudate was clear, resembling the white of an egg. The ointment and drops were tried in various types of keratitis, as well as in traumatic ulcers, marginal ulcers, and neurotrophic disturbances. In acute pneumococcus conjunctivitis the action of penicillin was rapid, and less painful but no more effective than that of one-percent silver nitrate. In chronic blepharitis penicillin was no more effective than the currently used remedies. This fact supports the accepted view that in chronic blepharitis the local infection is less important than general disturbances, such as hepatic insufficiency or allergy. Ray K. Daily.

Asnarez, Jose. Rapid dacryocystorhinostomy. Arch. de la Soc. Hisp.-Amér., 1944, v. 4, Nov.-Dec., p. 1064.

The merit which the author claims for this technique is chiefly the rapidity with which the operation may be performed. He completes it in 15 to 20 minutes. The steps of the operation are: the usual incision with a knife; dissection with scissors; introduction of a mastoid speculum into the wound; isolation of the sac with scissors; incision of the sac as posteriorly as possible; introduction of three fine silk sutures into the anterior lip of the sac, which are laid aside; denuding of nasal wall of periosteum; perforation of the lamina papyracea; separation of nasal mucous membrane with a Citelli forceps; rapid enlargement of the osseous opening to the desired size; cutting a

flap of nasal mucosa in the shape of a C, and joining it to the lacrimal sac by the three sutures; a skin suture and slightly compressive bandage complete the operation. The author doubts the importance of a smooth and regular bony aperture, and claims that there is less likelihood of injuring the nasal mucosa with forceps. In 200 cases, there were 4 percent failures.

Bordas, F., and Burch, M. The technique of dacryostomy. Arch. de la Soc. Hisp.-Amér., 1944, v. 4, Nov.-Dec., p. 1044.

This is a well-illustrated description

of the authors' technique of external dacryocystorhinostomy which they perform as an ambulatory operation. Burch designed eight burrs of various shapes and sizes, the purpose of which is rapidly to produce an adequate osseous opening into the nose without damaging the periosteal surface of the nasal mucosa. The incision into the lacrimal sac and the anastomosis with the nasal mucosa follows closely that of Dupuy-Dutemps. Fine silk is used for the sutures and a Beaupre epilation forceps serves most conveniently as needle holder for the fine needles. In order to keep the anterior flap from retracting backwards and blocking the new intranasal opening, the central suture of the anterior flap is brought out through the wound and tied to the skin suture. Two days after the operation the sac is irrigated through the lacrimal puncta. The nasal packing is discontinued on the fifth day and the cutaneous sutures are removed on the sixth or seventh day. Of 52 patients thus operated on, the results were satisfactory in 49. In one case the failure was due to a hypertrophied middle turbinate; in one to cicatricial bands within the sac, and in the third no reason for the failure could be discovered. (7 illustrations.)

Brausewetter-Koppner, G. Comparison between trephining (Elliot) and iridencleisis (Holth). *Klin. M. f. Augenh.*, 1942, May-June, v. 108, p. 303.

In order to allow a proper comparison of the effect of two fistulating antiglaucomatous operative procedures, Elliot's trephining was performed on one eye of 75 patients with bilateral glaucoma and Holth's iridencleisis on the other. After trephining 11 eyes required a second operation, after iriden-

cleisis 19 eyes. Four eyes were lost after trephining, one after iridencleisis had been performed, and 13 eyes were almost or completely blind before operation. Five trephined eyes became infected postoperatively, two of them immediately. All late-infected eyes were lost. In one case sympathetic ophthalmia resulted in total blindness of both eyes. Seven eyes developed cataract after Elliot's operation and four after Holth's. Free fistulation was observed after 11 trephinings and 6 iridencleises. Of fifty patients who were operated on only once in each eye trephining failed to reduce the tension in three and iridencleisis in four. Eleven trephinings and ten iridencleisis required at least a second operation. Thirty-five trephinings and 36 iridencleises were successful in preserving the function of the eyes, though some of these eyes were under observation for only one year. Trephining is the more dangerous operation because of the occurrence of infections. After iridencleisis no infections were observed. From the cosmetic standpoint trephining with peripheral iridectomy is preferable. The course of the glaucoma in both eyes of an individual patient did not differ regardless of which operation was used. (1 diagram, 1 chart, bibliography.) F. Nelson.

Carrasco, Guijarro. Short wave in ocular infections. *Arch. de la Soc. Hisp-Amér.*, 1944, v. 4, Nov.-Dec., p. 1079.

Two cases are reported. The first concerns a five-year-old child with a metastatic purulent endophthalmitis, subsequent to an acute exanthema. There was an enormous exophthalmos, extensive hard chemosis, evidence of pus within the eyeball, severe pain,

fever, and prostration. Short-wave therapy rapidly relieved the pain, and after the third or fourth treatment the general condition of the child was much improved; the child recovered with an atrophic eyeball.

The second patient had an orbital abscess as a complication of a severe erysipelas, which was treated by drainage and multiple incisions. The recovery was definitely accelerated by short-wave therapy. Ray K. Daily.

Cetner, J. A. Practical method for application of ophthalmic ointments. U. S. Naval Med. Bull., 1945, v. 45, Oct., p. 767.

To facilitate insertion of ointments directly into the conjunctival sac when collapsible tubes are not available, the use of an ordinary 2-c.c. glass syringe is suggested. It is particularly recommended in epidemics when large numbers of patients must be treated.

Morris Kaplan.

Chulia, Vicente. Repair of an extensive posterior symblepharon. Arch. de la Soc. Hisp.-Amer., 1944, v. 4, Nov.-Dec., p. 1070. (See Section 5, Conjunctiva.)

Costi, C. X-ray therapy in inflammatory ocular diseases. Arch. de la Soc. Hisp.-Amer., 1944, v. 4, Nov.-Dec., p. 1072.

Costi urges X-ray therapy in inflammatory ocular conditions which fail to respond to the usual therapeutic procedures. The dose required for inflammatory lesions is very small and is in inverse ratio to the intensity of the inflammatory process. He reports a grave case of bilateral cellulitis, and a case of severe corneal abscess which responded well to X ray irradiation, after failing to improve on sulfa drugs

and foreign-protein therapy. He uses irradiation in acute or subacute dacryocystitis to reduce the inflammatory process preparatory to surgery. This enables him to work with good anesthesia and hemostasis, which is difficult to obtain in the acute inflammatory stage. Ray K. Daily.

DeVoe, A. G. Surgery of the anophthalmic orbit. Amer. Jour. Ophth., 1945, v. 28, Dec., pp. 1346-1351.

Djacos, C. Modern tattooing of the cornea. Arch. d'Ophth., 1945, v. 5, no. 1, p. 36.

The author gives a historic review of the subject of corneal tattooing and describes in detail both the method of Knapp in which gold chloride is employed and that of Rollet who injects a nonabsorbable coloring matter into the leucomatous cornea. The latter method is favored. The author injects a 2-percent solution of India ink into the corneal stroma in the proper location by means of a special metal syringe designed by Raison. In cases of extensive leucoma two or three punctures are made and great care is taken not to inject an amount which elevates the corneal epithelium. Five cases are cited in which satisfactory results were obtained. After two years there was no attenuation of the coloration or migration of the pigment.

The method of Knapp has the disadvantage that the solution of gold chloride is caustic and requires neutralization. From 1- to 4-percent solutions are employed according to the thickness and whiteness of the leucoma. Two cases are reported. In one the cosmetic result was good, but in the other the pigmentation was not uniform. Djacos notes that there is a marked

uveal reaction and that patients complain of much postoperative pain. Furthermore the coloration is not permanent and repetition of the tattooing is necessary after a period of several years. There is also a tendency towards vascularization of the impregnated area.

Phillips Thygeson.

Fassbind-Knapp, Dora. **Condensed survey of the technique and results of chemical tattooing of the cornea.** *Klin. M. f. Augenh.*, 1942, May-June, v. 108, p. 262.

The advantages of tattooing the cornea with gold chloride and other metallic salts, especially platinum chloride, are the simplicity of the process, the comparatively insignificant postoperative irritation, the possibility of treating thin and adherent scars without danger of perforation, the rarity of postoperative complications and the beautiful cosmetic result. A disadvantage is the frequent impermanence of the result, which, however does not exclude repetition of the process. A good cosmetic result may last for several years. The method is contraindicated when the corneal tissue is seriously impaired or where inflammatory processes are still active. The article contains a history of corneal tattooing, a discussion of methods, clinical observations, advice about the use of different metallic salts, a statistical survey, and some histologic findings. She also mentions the possibility of tattooing the palpebral conjunctiva of albinos to eliminate some of the glare and adds observations about the deposition of gold into the cornea in patients who have been treated with colloidal gold solutions (sanocrysin) intravenously. (2 microphotographs, bibliography)

F. Nelson.

Friede, Reinhard. **The treatment of ocular infections with sugar.** *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 404-410.

In ophthalmology sugar is used therapeutically in two ways: 1. Intravenous injections of 20- to 50-percent dextrose solution to reduce tension by removing water. 2. Local application to cornea and conjunctiva where too the basis of action is a reduction of swelling by osmosis. The author has experience with 60 cases of ocular disease and finds diseases of the anterior and middle layers of the cornea susceptible to this form of therapy. It has been most promising with clearing of corneal transplants which have become clouded.

F. Herbert Haessler.

Gradle, H. S. **Prevention of wound rupture after cataract extraction.** *Anal. Argentin. de Oft.*, 1944, v. 5, Jan.-Feb.-March, pp. 13-16.

Postoperative corneoscleral ruptures may be classified as simple fissure of the incision, frank rupture with destruction of new-formed capillaries and hyphema, and extensive rupture with iris prolapse. In 200 consecutive cataract extractions, the author claims an incidence of 35 percent the first type, 15.5 percent of the second type, and 2.5 percent of the third most serious group. There was no correlation between these ruptures and the ability of the surgeon or the procedure employed.

Gradle feels that the genesis of wound rupture may be traced to pressure on the globe by the orbicularis muscle, in conjunction with the recti. To overcome this hazard, he performs an oblique tenotomy of the orbicularis muscle near the outer canthus in both lids, with a subsequent marked reduction in the incidence of all types of

cataract-wound rupture. (3 illustrations.)
Edward Saskin.

Hartmann, Karl. The treatment of anomalies of the position of the lids by means of electrocoagulation. *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 342.

Scarring of the conjunctiva in ectropion with silver nitrate, sulfuric acid, or Paquelin cautery has been used for years in order to shorten the surface of the conjunctiva and to straighten the lid. The author used electrocoagulation with the diathermic needle for the treatment of entropion and ectropion. This method is recommended especially for cases of senile ectropion and eversion of the lacrimal puncta with epiphora. The result is said to be more complete and permanent because extensive scars develop in all the tissues of the lid. Several rows of point-like diathermy punctures are placed in the conjunctiva in ectropion and in the skin of the lid in entropion. (4 case reports, 2 drawings, literature excerpts.)
F. Nelson.

Himmelmann, W. Scopolamine-enedodal-ephetonin injections in ophthalmology. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 214-217.

The author recommends this form of general narcosis for ophthalmic surgery, particularly in strabismus, retinal detachment, and plastic surgery. In 370 operations there were no circulatory mishaps. (References.)

Karbucher, P. Combined corneal abrasion and iridectomy in cases of metaherpetic parenchymatous keratitis, corneal tuberculosis and other corneal inflammation combined with iridocy-

clitis. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 184-187.

The author reports nine brief case histories to illustrate very satisfactory results from the application of the surgical procedure described in the title. The procedure was devised by Vogt.
F. Herbert Haessler.

Kötz, H. A statistical study of hemorrhage after operations for senile cataracts. *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 291.

The author presents a statistical analysis of the postoperative hemorrhages which occurred after extraction of 750 senile cataracts in the years 1938 to 1940. In the group of 440 otherwise uncomplicated senile cataracts hemorrhages occurred in 18.9 percent, most frequently on the 4th or 5th day. The percentage of hemorrhages after intracapsular extraction was almost twice as high as after extracapsular extraction. The greatest number of hemorrhages was found in December. In females the occurrence of hemorrhages increased with advancing age. Males were particularly predisposed in the fifth decade of life. Controlled diabetics were not more predisposed to bleeding, nor were hypertonics, provided they were preoperatively treated with ample bleeding. Glaucomatous patients were equally predisposed to hemorrhages as arteriosclerotics. Postoperative hemorrhages not only influence the duration of hospitalization (average 23 days as against 18 days in uncomplicated cases) but also the final result of the operation. Kötz recommends saturating doses of vitamin C in the preoperative and postoperative period for all cataract patients. (Bibliography.)

Lehrfeld, L. Revaluation of Her-

bert's flap operation for glaucoma. Arch. of Ophth., 1945, v. 34, Sept., pp. 191-194. (See Section 8, Glaucoma and ocular tension.)

Leopold, I. H. Local toxic effect of detergents on ocular structure. Arch. of Ophth., 1945, v. 34, Aug., pp. 99-102.

A number of detergents are in use in ophthalmology as germicides and cleansing agents but more particularly to aid in the penetration of therapeutically active substances through the cornea. Experiments were conducted on the normal and on the abraded rabbit cornea to determine whether or not the detergents exerted a local toxic effect on the eye. The agents tested were Aerosol OT, Aerosol OS, Tergitols 4 and 7, Tergitol 08, Zephiran, and Duponal ME dry.

It was found that repeated application of detergent solutions produced conjunctival damage in concentrations as low as 0.1 percent. Zephiran chloride in this concentration produced corneal damage. Repeated applications of higher concentrations of all of the agents tested produced superficial corneal changes in normal rabbits. Regeneration of corneal epithelium was retarded by the repeated application of solutions containing 0.5 percent of each detergent and to a slight degree by solutions of 0.1 percent. The tissue damage resulting from one application of the undiluted agents is reparable. The damage observed is in the cornea and conjunctiva with no involvement of the deeper structures. These studies do not contraindicate the use of the detergents; they simply call attention to the toxic property of these compounds.

John C. Long.

the eye. Klin. M. f. Augenh., 1942, v. 108, May-June, p. 319.

Since the introduction in 1930 of diathermy as a method for closing tears of the retina, the use of diathermy has been considerably expanded. Weve, Imre, and Csapody reported successful destruction and cure of an intraocular malignant melanoma. After a complete blockade of the whole area surrounding the tumor the latter was burned out with electric-wire cautery. Since no exact data concerning the strength of the current nor the duration of its application in such operations have been published the author undertook to find out these requirements experimentally in rabbit's eyes. One series of eyes was enucleated immediately after the operation, another after one week, and a third after two months and examined histologically. In all eyes a thorough destruction of the retina was found in the treated area. Extensive hemorrhages were also always present. The diathermic coagulation not only acts locally but leads to considerable hyperemia and hemorrhages in more distant areas of the eye because it raises the intraocular temperature. The effect of a known strength of current varies with several factors, such as more or less perfect contact between the electrode and the sclera, dryness of the field of operation, and degree of local hyperemia. Histologically no thrombosis of the vessels was found, and hyperemia was still considerable on the seventh day after operation. The author was unable to produce a complete coagulation blockade of the area where a tumor was anticipated. The strong reaction of the choroid, excessive hyperemia, and the lack of thrombosis in all eyes, whether treated with a current of 40 to 50 or 60 to 70 milliamperes for

Lugossy, G. Effect of diathermy on

one to three seconds, showed that the necessary strength of the current and the optimal time of application have not yet been determined and that further research is required to avoid grave danger in treating malignant uveal tumors with diathermy. (6 microphotographs, bibliography.) F. Nelson.

Luzsa, Andreas. The effect of silver-nitrate solution dropped in before an eye operation. *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 231-234.

To render harmless pathogenic germs present on the human conjunctiva, at least for a certain danger period, it is recommended to instill a 1-percent silver-nitrate solution on the bulbar conjunctiva of patients who are undergoing an operation which opens the globe. This should be done after giving the local anesthetic, and immediately before the operation is performed. Culture tests, as well as clinical experience with conjunctival irrigation fluid proved the value of this procedure. Possibly the thin and invisible coagulation membrane produced by silver-nitrate solution fixes, at least for the duration of the operation, any germs still present. (References.) F. Nelson.

Malbrán, Jorge. Restoration of the socket or the lower cul-de-sac after enucleation. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Aug., p. 394.

After a brief review of the different operations for the reconstruction of the socket or conjunctival cul-de-sac, the author describes Wheeler's operation and considers it the ideal procedure because of its simplicity and excellent results. (Bibliography.)

Plinio Montalván.

Malbrán, J., and García Nocito, P. F. Burch's operation. *Arch. de Oft. de*

Buenos Aires, 1943, v. 18, Aug., pp. 399-404.

Based on their experience, the authors prefer Burch's operation to enucleation. This consists of evisceration with implantation of a gold or lead-free glass sphere in the scleral cavity. They used vitallium and lucite spheres, preferably the latter. The implant has never been expelled in any patient. (1 illustration.)

Plinio Montalván.

Moreu, Angel. Goniotrabeculotomy and goniocyclodiathermy. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Nov.-Dec., p. 1011.

The author's procedure seeks to combine the advantages and eliminate the undesirable features of Barkan's goniotomy and Vogt's cyclodiathermy. He does not agree with Barkan on the important role which sclerosis of the walls of Schlemm's canal and obstruction of the pectinate ligament with detritus or pigment have in the pathogenesis of primary glaucoma. In ten years of gonioscopic study he never encountered the signs described by Barkan as indicative of sclerosis of the walls of Schlemm's canal. The usual finding is an edema of the ciliary body accompanied by a slight exudate which penetrates the meshes of the pectinate ligament and gives rise to peripheral synechia; new blood vessels form around Schlemm's canal, and exudates finally obliterate the angle of the anterior chamber. The typical glaucomatous lesions consist of an edema of the uvea and a resultant irido-cyclo-choroidal stasis. The author believes that goniotomy is indicated only in trabecular, infantile, absolute, and malignant glaucoma, and in hypertension secondary to uveitis. The presence of peripheral

synechiae is a contraindication to goniotomy; in such cases separation of the iris is followed by a hemorrhage, and an examination several days later reveals a re-formation of the synechiae, sometimes in increased numbers. Post-operative examination of patients treated by goniotomy revealed that the main defect of this procedure is the increased formation of trabecular synechiae which leave the angle of the anterior chamber in a worse state than it was before the operation. It occurred to the author to supplement goniotomy with diathermy. The advantage of this procedure over Vogt's cyclodiathermy consists in the more direct approach to the ciliary body, in reducing the numbers of punctures, and in not disturbing the pericorneal vascular network. With the gonio-cyclodiathermy the peripheral synechiae are divided without hemorrhage, and the edematous areas of the ciliary body are coagulated relieving the stasis and edema of this area; the coagulated areas, surrounded posteriorly by an inflammatory zone leave an atrophic cicatrix. In this operation there are two distinct procedures which may be used separately or combined: cutting with an electric current and diathermy puncture. The operation is performed under gonioscopic guidance through a Koeppe contact lens which has a perforation on the side large enough to permit the passage of a Ziegler knife-needle. The knife-needle is introduced through the cornea, passed through the anterior chamber, and fixed in the synechia; it is then connected to a diathermy terminal, and a current of 60-70 milliamperes is used to cut the synechia. For coagulation of edematous areas in the ciliary body a fine needle 1.5 mm. in diameter is intro-

duced in the same manner, and 40-50 milliamperes of diathermy passed through the area; 6 to 8 such punctures are made. In the combined procedures it is preferable to begin by coagulation, cutting the synechiae afterwards. The author believes that this operation is indicated in all cases where a goniotomy or cyclodiathermy is considered. (2 illustrations, 6 graphs.)

Muldoon, W. E. Restoration of patency of nasolacrimal duct. *Amer. Jour. Ophth.*, 1945, v. 28, Dec., pp. 1340-1345.

Mylius, Karl. Dimming of the psyche in ocular surgery. *Klin. M. f. Augenh.*, 1941, v. 107, Sept., pp. 225-230.

After paying tribute to Koller, who first applied cocaine as a local anesthetic for eye operations, Mylius points out that it is sometimes desirable or necessary to supplement local anesthesia with an agent that is not a general anesthetic but which puts the patient completely to sleep. Morphine has a number of well-known disadvantages. Avertin, per rectum or intravenously, has not fulfilled expectations. Evipal sodium represented a definite improvement but sometimes produced undesirable incidental and secondary effects, such as muscle jerks, sneezing, coughing, and defense movements. A combined solution of scopolamine-eucodal-ephedrin (S.E.E.—Merck) which can be injected intravenously and should be administered after the patient has entered the operating room, is superior to all previous agents, since with it undesirable by-effects are not observed. It does not put the patient to sleep but dims his emotions and eliminates anxiety even in very nervous and excited persons. It

produces complete equanimity but not unconsciousness, so that the patient never loses control and is always able to coöperate intelligently with the surgeon. Even such prolonged operations as retinal detachment can be carried out safely with this method. Combined with local anesthesia the analgesic effect of S.E.E. is strong enough to allow otherwise painful operations, for example, acute glaucoma and strabismus operations, to be performed absolutely pain free. The postoperative value of S.E.E. includes absolute relaxation of the patient and a pain-free period of many hours after the operation.

Poleff, L. The real value of treatment by sulfonamides in trachoma. *Ophthalmologica*, 1943, v. 105, March-April, pp. 156-174. (See section 5, Conjunctiva.)

Rhode. The mechanism of action of the sulfonamides and their significance in ophthalmology. *Klin. M. f. Augenh.*

1942, v. 108, Jan.-Feb., p. 1.

Many theories have been advanced concerning the mode of action of the sulfonamides on bacteria in vitro and in vivo. None of them have been absolutely satisfactory nor explained fully the effect of the various sulfa drugs. Some authors believe that formation of peroxides in the organism is responsible for the destruction of germs in the body, others that sulfa drugs produce an increase of phagocytosis or a wall of leucocytes to stop the invasion of bacteria. It seems certain that bacteria are damaged by the drugs, particularly in vivo, and their growth stopped to a certain degree. Bacilli require certain substances in order to grow; e.g. p-amino-benzoid acid, which is probably formed by the bacteria themselves. Since p-amino-benzoic acid apparently is antagonistic to sulfonamides and can render them ineffectual this substance may be responsible for the ineffectiveness of sulfonamides in cultures.

In the field of ophthalmology sulfa drugs have been used with success locally, orally, and parenterally for combatting various bacterial and virus infections such as iridocyclitis with hypopyon, vitreous abscesses, dendritic and herpetic keratitis, corneal ulcers, infections of the lids, gonorrheal ophthalmia, and trauma. Prontosil, sulfanilamide, and sulfathiazole have been most used. (Bibliography.)

Rossi, Silvano. Irradiation of the cervical sympathetic in arterial hypertension. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Nov.-Dec., p. 1023.

Reference is made to a former publication on the efficacy of irradiation of the cervical sympathetic in glaucoma.

(Casanova "La irradiacion del simpatico cervical en el glaucoma-Clinica"). In this presentation the author wishes to add another indication for this procedure, that is, the reduction of the intraocular pressure in cases in which surgery was inadequate. The experience with postoperative irradiation gives the impression that in addition to mechanical factors controlled by surgery, there exist in glaucoma complicated processes directly under control of the neurovegetative nervous system, which respond to irradiation of the cervical sympathetic, thus achieving a satisfactory result which is not obtained by surgery alone. He describes a patient who still had an average tension of 48 mm. Hg after an Elliott trepanation. After three irradiations the tension was reduced to 22 mm. Hg and remained at this level without the use of miotics. Casanova also reports observations on three patients in whom the tension remained normal for almost two years after it had been reduced by irradiation. On the basis of this experience the author urges that irradiation of the cervical sympathetic be tried before subjecting the patient to a second operation. Assuming that a neurovegetative neurosis is an important factor in the development of glaucoma, irradiation is probably effective by presenting a barrier to the transmission of impulses, and freeing the eye from the excessive influence of the sympathetic nervous system. The clinical effect of the irradiation on the eyes is more lasting than the inhibition of the sympathetic itself. This suggests that a readjustment has probably taken place in the ocular tissues and blood vessels. Experimental irradiation on animals indicates that irradiation acts on the synapse within

the ganglion, altering its capacity to conduct stimuli, possibly by a change in cellular permeability. Retinitis pigmentosa and organic and functional obstruction of the retinal vessels are suggested as fields of investigation for this form of therapy. Ray K. Daily.

Schultz, A., and Jaeckle, C. E. Plastic surgical repair about the eyes with free grafts. *Arch. of Ophth.*, 1945, v. 34, Aug., pp. 103-106.

The surgical correction of scarred deformities about the eyes has assumed increasing importance as the result of war injuries. It is preferable to have plastic surgical procedures about the eye performed by the properly trained ophthalmic surgeon because of his special knowledge of the physiology and anatomy of the eye and its adnexa. The authors review the technique and indications for the use of mucous-membrane grafts, free epithelial grafts, and free full-thickness grafts. The use of the mucous-membrane graft is illustrated in the correction of a symblepharon produced by a lime burn.

As an illustration of the use of free epithelial grafts the authors report a case of plastic repair of the orbit by epithelial inlay. A full-thickness free graft was used to correct a cicatricial defect of the upper lid.

Thiel, R. The mydriatic effect of various sympathetic stimulants (aryl-alkylamines). *Klin. M. f. Augenh.*, 1942, v. 108, Jan.-Feb., p. 10.

A. Experimental section: The effect of twenty different substances of the aryl-alkylamine group on human eyes were exactly recorded under uniform conditions. The intensity of light was uniform and relatively high in order to approximate the condition of clinical examinations. The size of the pupils was measured with Landmann's pupilometer, accommodation was tested with Adam's accommodometer, the intraocular pressure with Schiøtz's tonometer (model 2). Instillation was done while the patient was in a horizontal position. Standardized pipettes were used in order to safeguard uniformity in size of drops. Usually 15 persons were subjected to the test with each substance. With substances which produced irritation of the eye and apparently had little or no effect on the pupils a smaller number of tests was made. The age of the persons used varied since it is known that pupils of young people dilate more readily and extensively than those of older ones. (The following chapter has to be read in the original since it would not be understandable without the help of the given chemical structural formulas and curves.) The experiments gave evidence that the strongest mydriatic effect can be obtained with primary amines as 1-phenyl-2-amino-propan. The secondary related amines have a much lesser effect and the tertiary bases are not effective at all.

B. Clinical section: For diagnostic purposes it is desirable to have a drug

which dilates the pupil quickly and extensively, and produces a mydriasis of short duration. It is also desirable that the pupillary reaction to light be abolished, that accommodation and intraocular pressure (glaucoma and preglaucoma) are not affected, that mydriasis can be reversed by application of miotics at any time, and that the drug is tolerated well. Therapeutically the amines are useful in many cases where cycloplegics like atropine, scopolamine, and homatropine, do not produce the desired dilation (iritis, iridocyclitis) and where an additional mydriatic effect is desired. The amines can be used in combination with cycloplegics in the form of drops or ointments. The effect of the amines is due to irritation of the sympathetic fibers of the dilator of the iris. (18 graphs, 2 charts, 4 photographs, report of 10 cases.)

Von Sallmann, L. Penetration of penicillin into the eye. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 195-201.

This paper reports additional work by the author on the penetration of penicillin into the eye when used locally. Three local methods, designed to introduce comparatively high concentrations of drugs into the anterior segment of the eye, were tested on rabbits and the results compared. The methods were subconjunctival injection, iontophoresis, and the application of cotton packs saturated with a solution of penicillin.

After the subconjunctival injections the author noted that the conspicuous bulging of the conjunctiva visible for four to six hours was apparently due to the accumulation of tissue fluid, since the concentration of penicillin in the aqueous and tissue extracts decreased

steadily after the first hour. There was no indication that any of the examined fluids and tissues retained penicillin for more than six hours.

The solution of penicillin injected contained 5,000 Oxford units per c.c. It is questionable whether solutions of this strength can be employed subconjunctivally in the human eye without producing a severe reaction. In two patients a solution containing 2,000 Oxford units per c.c. caused obvious discomfort.

A comparison of the three methods showed that the highest concentration was obtained in the aqueous by iontophoresis, and in the cornea, the iris and ciliary body by the prolonged application of cotton packs. The lowest concentration of penicillin in the aqueous, the cornea, and the iris with ciliary body was observed after subconjunctival injection.

Extremely high concentrations of penicillin were found in the cornea, the iris, and ciliary body after the application of cotton packs saturated with a solution of sodium penicillin containing 20,000 Oxford units of penicillin per c.c. The penicillin content of the aqueous was also higher than that obtained with the other methods tested.

The depletion of penicillin from the ocular tissues and the aqueous was almost complete eight hours after iontophoresis with a solution of sodium penicillin containing 5,000 Oxford units of penicillin per c.c. and after application of cotton packs saturated with a solution containing 20,000 Oxford units per c.c.

In general, not more than traces of penicillin were demonstrated in either the lens or the vitreous after topical administration.

Determinations on four human eyes

with normal and with edematous corneas gave more erratic results and much lower values than determinations on rabbits' eyes. R. W. Danielson.

Wright, R. E., and Stuart-Harris, C. H. Penetration of penicillin into the eye. *Brit. Jour. Ophth.*, 1945, v. 29, Aug., pp. 428-436.

Twelve cases are reviewed in which various methods of penicillin administration were used. In five of these cases the fluids showed detectable inhibitory action. Penicillin reaches the aqueous humor when given by local irrigation or by intramuscular injection, but the concentrations obtained are variable and often low. By the use of iontophoresis, higher intraocular concentration can be obtained. The fluid from the three eyes treated by ionization showed definite bacteriostasis. In only one of the eyes treated by irrigation was a comparable inhibition obtained.

At present it is impossible to define the concentration of penicillin necessary for therapeutic effect in either blood or tissue fluid. It may be that the small amounts of penicillin reaching the aqueous humor after intramuscular injections or irrigations will prove to be clinically adequate, but the fact that high intraocular concentrations can be obtained by iontophoresis is worthy of further investigation. PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Birch-Hirschfeld. Disturbances of the light sense in aviators. *Klin. M. f. Augenh.*, 1942, v. 108, Jan.-Feb., p. 56.

As already pointed out by Italian authors, especially Colojani, ocular and

extraocular factors play a part in the deterioration of the light sense of flyers. Of importance are: 1. vitamin-A deficiency, 2. diseases of the liver and other general pathologic conditions, 3. neurovegetative disturbances, 4. decrease of atmospheric pressure, 5. diseases of the nose and labyrinth. When a group of aviators has been transferred to a new and different environment a reexamination of the light sense of such personnel is advisable.

F. Nelson.

Comberg, W. The ring defect in the visual field of wearers of glasses. *Klin. M. f. Augenh.*, 1941, v. 107, Dec., pp. 585-589.

An inherent defect exists in spectacle lenses which is well known but possibly generally neglected when considering a patient's difficulties in accustoming himself to his first glasses. A concave lens reduces the image of that part of the object which is seen through it. Consequently a second image of those parts of the object which are seen through the marginal zone of the lens is seen just beyond the limits of the lens. This produces a diplopia which is sometimes disturbing. A convex glass enlarges the image, consequently the part of the image seen through the marginal zone of the lens overlaps the adjacent image and produces a zone of blurring which in effect cuts out a portion of the object. Comberg has measured and recorded graphically the distance at which glasses of varying dioptric power cut out (+ lens) or duplicate (- lens) a zone 20 cm. wide, roughly the size of a human head. (2 graphs.)

F. Herbert Haessler.

Costi, C. Nocturnal myopia, sugges-

tions of ophthalmic interest. *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 621-627.

Nocturnal myopia is defined in the following way: When the brightness of an object observed by an eye of normal accommodative power is low, the distance of the punctum remotum is reduced. The average value obtained is two diopters, that is, the eye is made myopic to that degree. The test demonstrating this phenomenon is made by projecting a luminous cross on a screen. With ordinary illumination the cross is seen clearly, but as the illumination is reduced the cross becomes blurred. The cross is again seen clearly as minus lenses are introduced up to two diopters.

The fact that neither atropinized eyes nor eyes with advanced presbyopia show the phenomenon seems to indicate that the mechanism is accommodative. Based on the above observation the assumption is that eyes of normal accommodative power have from 1.5 to 2.00 diopters of negative accommodation. A practical application is cited. A myopic chauffeur who had normal vision in the day time with glasses of -2.00 D. complained of seeing poorly at night. It was found that by increasing the strength of his glasses to -3.25 he saw very well and without fatigue for prolonged night driving. (3 figures.)

Göthlin, G. F. Inheritance of congenital total color blindness with photophobia. *Acta Ophth.*, 1941, v. 19, p. 202.

The author refers to his publication in 1924 on this subject, which gave some indication of the fact that congenital total color blindness with photophobia was probably of a hereditary nature. At that time, however, the literature did not contain a family tree in which this heredity was directly demonstrable. Nettleship's report of 1880 the author does not consider sufficiently reliable, because the family contains in addition amaurotic idiocy and mental defects. It was obvious, however, from the available material that this anomaly was not inherited as a dominant, and if its heredity was recessive it was not sex linked. In the present study the author tabulates the compiled material of this century, which consists of 41 publications, reporting on 41 families, with a membership of 254, and 76 affected members. A report of three family trees, with one homozygotic and one heterozygotic parent, shows a membership of 16, with 9 affected. Statistical analysis of these tables shows that total color blindness with photophobia may be transmitted to future generations. The heredity is recessive and not sex-linked. The author's figures show preponderance of women among those involved; this does not agree with the findings of Nettleship, Peter, and Waardenburg, who found preponderance of men. The author attributes the discrepancy to inadequacy of material at the disposal of the former investigators. Consanguinity among parents was found in 32 or 33 percent of the European families.

Because of sex-linked inheritance of

partial color blindness and the recessive inheritance of total blindness, the type of heredity in an atypical case may determine whether we are dealing with a severe case of partial color-blindness or a mild case of total color-blindness with photophobia.

Jancke, G., and Holst, A. Influence of heredity and environment on the development of refraction in twins. *Klin. M. f. Augenh.*, 1941, v. 107, Oct., pp. 373-389.

This study is based on the measurement of corneal curvature in 140 pairs of twins (72 single-ovum, 68 two-ovum) and of the total refraction of 60 pairs of twins of each kind. The striking preponderance of concordance of findings in single-ovum twins demonstrates the heredity of refractive states. This is true for hyperopia, emmetropia, and myopia alike, though astigmatism seems to be influenced somewhat by environmental factors. Environmental factors do not produce changes that increase with age. Near-work in no way alters the development of the refractive state even in myopia. School myopia in any genetic sense does not exist. The name "school myopia" indicates coincidence in time only and should be dropped because it is misleading. (6 tables, references.)

F. Herbert Haessler.

Györfy, S. The role of the fluid used for filling contact lenses. *Klin. M. f. Augenh.*, v. 108, May-June, p. 328.

Solutions used for filling the space between a contact lens and the cornea have to fulfill certain physical and chemical requirements. The refractive index must approximate that of the cornea and chamber fluid; i.e., 1.335. Chemically the solution must resemble

the tears in composition and pH, and be isotonic with them. The pH of tears varies between 7.0 and 8.4, and the values in an individual can be established with sufficient accuracy by the use of a colorimetric indicator paper of which a narrow strip is put into the lower cul-de-sac. Several buffer solutions have been advocated, and the required mixtures for the various degrees of pH are given in form of a chart. The pH may change with the length of time a contact lens is worn. Since the gaseous exchange of the cornea is eliminated to a high degree when it is not in contact with the air, a lack of oxygen and increase of CO_2 between contact lens and cornea will result in a shifting of the pH towards the acid side. When plastic contact lenses are used the author frequently noticed a rather sudden decrease of visual acuity which was caused by incomplete wetting of the inner surface of the lens, leaving small dry areas. They are probably caused by peculiar surface tension between the plastic material and the fluid. Certain protein preparations as caseosan, actoprotin and especially lamepon were used satisfactorily in the attempt to lessen the surface tension. (References.) F. Nelson.

Karpe, G. The fitting of spectacle lenses. *Klin. M. f. Augenh.*, 1942, v. 108, Jan.-Feb., p. 80.

The author presents a mathematical and general practical discussion of the general principles of fitting glasses, including measuring of pupillary distances, adjustment of glasses, properly centered and at a proper distance from the corneal vertex. Karpe also discusses in detail the influence of the presbyopic additional near correction on the convergence of the eyes and the prismatic

effect of decentration. Since it is not possible to give an understandable account of the various mathematical calculations without presentation of the accompanying tables and charts it is recommended that one read the article in the original for additional information. (4 figures, 4 charts.) F. Nelson.

Kayser, B. An attack of total color blindness accompanied by sensation of unusual brightness and scintillating scotoma. *Klin. M. f. Augenh.*, 1942, May-June, p. 362.

The author experienced a rare phenomenon consisting of complete sudden extinction of the color perception during the day in a normally lighted room. While all color values disappeared in the faces of three persons with whom he was talking, everything became unnaturally bright. The phenomenon lasted for five minutes and was not accompanied by scintillation. He believes it probable that a vasomotor spasm occurred in identical areas of the subcortical region of the right and the left occipital lobes of the brain. The author also had innumerable attacks of scintillating scotoma during his long life, sometimes 2 or 3 during one day but never accompanied by headaches or vomiting. On one occasion he experienced a colored scintillating scotoma while walking briskly in the dark. Suddenly bundles of fiery colored rays appeared before both eyes shooting upwards like beautiful fireworks. After five minutes the phenomenon disappeared and was not followed by headache or malaise. The vision was not impaired and the phenomenon never recurred.

F. Nelson.

Lisch, K. On the question of the

genesis of myopia. Klin M. f. Augenh., 1941, v. 106, June, pp. 695-699.

In the last five years most oculists have come to believe that myopia is not produced by exogenous factors but congenitally. Recently Lindner has resurrected the old concept of "school myopia" and has suggested that the only way to come to a definite conclusion is to separate single-ovum twins before they go to school so that one may be sent to a village school and allowed to become a peasant while the other is trained for the life of a scholar. This program could hardly be carried out, but Lisch has records of two pairs of single-ovum twins in which the conditions of this experiment were approached though it had not, of course, been planned.

Of a pair of sisters aged 30 years, of peasant stock, one became a seamstress after leaving primary school and the other an agricultural worker. Each developed high myopia which was greater in the right eye—namely, 17.00 and 11.00 D. combined with a small cylinder in the eyes of the seamstress, and 16.00 and 13.00 D. in the agricultural worker.

In each of the other pair of twins a high myopia of approximately equal amount occurred, suggesting a hereditary factor though there was no difference in their environment or activity as required for Lindner's "experiment." (References.) F. Herbert Haessler.

Matas, Carreras. New procedures for the subjective correction of ocular astigmatism. Arch. de la Soc. Hisp.-Amer., 1944, v. 4, Sept.-Oct., p. 733.

This article contains a detailed explanation of the physiologic optics involved in use of the astigmatic dial. The subjective test as used by Matas is based on the mathematical rules applied by Lindner to cylinder retinoscopy. In-

stead of the astigmatic band in the pupil which serves as the indicator in retinoscopy, the blackest line on the dial as seen by the patient serves as indicator in this test. If the axis of the correcting cylinder corresponds exactly to the axis of ocular astigmatism as indicated by the patient, the correction is simple. If, however, the axis of the correcting cylinder deviates from the axis of ocular astigmatism, the two cylinders placed at oblique axes to each other give rise to a new cylinder the axis of which will be somewhere in the acute angle formed by these two axes, and the patient will then see blackest another line, the axis of which will not coincide with the line which he saw blackest originally nor with a line perpendicular to it. The position of this new line, just as the position of the astigmatic band in retinoscopy, indicates the relative strength of the correcting cylinder to the patient's astigmatism, and the direction in which the correcting cylinder is to be moved to coincide with the axis of the ocular astigmatism. This technique, the author claims, has the merit of Marquez's bicylindric refraction, in that it relaxes the ciliary muscle through constant and rapid variation in strength and axis of the cylinder.

Ray K. Daily.

Meitner, H.-J. Peculiar case of anomaly of "blue sense." Klin. M. f. Augenh. 1941, v. 107, Sept., p. 293-301.

Meitner records congenital lack of blue perception in the eyes of a man with otherwise normal findings (except an unspecified refractive error). In the whole color circle blue, blue-violet, and violet were seen as neutral gray. Purple-red was seen as red. Rayleigh's equation was correct and Ishihara's pseudoisochromatic tests normal. On Nagel's charts yellow and blue were

differentiated, the latter being called gray. The case is probably one of atypical tritanomaly. Typical tritanopia could be ruled out. (References.)

Mihályhegyi, G. Improvement of visual acuity with contact glasses in the presence of lesions of retina and choroid. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 200-205.

In seven nearsighted patients with fundus lesions the correction of the refractive error by means of contact glasses gave much greater visual acuity than correction with ordinary lenses, presumably because a contact glass magnifies the image in a myopic eye. (References.) F. Herbert Haessler.

Oberhoff, Kurt. Hyperopic astigmatism and hyperopia in single-ovum twins. *Klin. M. f. Augenh.*, 1941, v. 107, Dec., pp. 577-580.

Oberhoff reports refraction of two pairs of single-ovum twins. The findings are in harmony with the theory that the refractive state is congenital. (3 figures.) F. Herbert Haessler.

Paterson, A., and Zangwell, O. L. Disorders of visual space perception associated with lesions of the right cerebral hemisphere. *Brain*, 1944, v. 67, Dec., p. 331.

The authors describe the case histories of two men who received compound fractures in the right parieto-occipital region. Damage from contusion was minimal. The angular gyri were injured. Of interest are the high grade visual and constructional disabilities which appeared after recovery from the injury. The disabilities were of three main types: 1) Unilateral visual symptoms: impairment of visual perception, relative hemianopia and

disorientation, and a tendency to neglect the left half of visual space. 2) Oculomotor symptoms: abnormalities of oculomotor coördination in reading and other tasks which demand a regular pattern of sequence of eye movements. 3) Visual constructive disabilities: a complex disorder affecting perception, appreciation, and reproduction of spatial relationships in the central field of vision. R. Grunfeld.

Sánchez Mosquera, M. Myopia corrected surgically. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 628-630.

Two cases of myopia were operated upon by excision of a strip of conjunctiva 6 or 7 mm. wide all around the limbus and 3 mm. from it. In the first case the myopia was reduced from -1.50 D. each eye to $-.50$ O.D. and $-.12$ O.S. In the second case the myopia was reduced from -1.75 to $-.25$ O.D. and from -4.75 to -3.75 O.S. The mechanism of this lessening of myopia was thought to be a flattening of the anterior segment of the globe by cicatricial contraction in the region of the excised conjunctiva.

Schumann, A rhythmic phenomenon in the field of vision. *Klin. M. f. Augenh.*, 1942, v. 108, Jan.-Feb., p. 97.

The author observed the appearance of a subjective light phenomenon in his visual field which consisted of groups of numerous small stationary red discs of different sizes, and fine scintillating bluish specks. Two pairs of such groups are visible in the visual field of each eye. The phenomenon appears and disappears in rhythmic intervals, increasing for 2-3 seconds, clearly visible for 3-4 seconds, gradually disappearing within 13-19 seconds

and then starting again. The author has been observing this phenomenon for about sixty years and does not think that it is a hallucination. (2 drawings)

Sloane, A. E. Refraction clinic. Amer. Jour. Ophth., 1945, v. 28, Nov., pp. 1259-1260.

Strebel, J. Morphology and genesis of posterior sclerectasia in high myopia and the inheritance of myopia. Klin. M. f. Augenh., 1941, v. 107, Aug., pp. 179-193.

Posterior sclerectasia or staphyloma posticum verum must be very rare because in recent discussions of the topic in works like the Kurzes Handbuch the author of the article does not even have an illustration of his own. Strebel refers to the literature and his own early description and now adds eight illustrations which he himself drew from patients in his care.

Most staphylomas are partial but an occasional one is total. Usually they involve the nasal side of the disc, more rarely they are temporal, and the latter are almost always bilaterally symmetrical. The nasal ones are often in the form of multiple terraces on which the vessels descend as cascades. The fundus is usually pale so that the choroidal vessels are visible. The lesion is almost always associated with a disturbance of macular pigmentation and often with other congenital lesions such as cataract and persistent pupillary membrane. Heredity is usually demonstrable.

The pathogenesis of staphyloma as well as the extreme myopia which accompanies it is clear from consideration of the above clinical material. There can be no question of mechanical stretching of the bulbus. The lesion is

purely an inherited degenerative form for which we have to thank our domestication. The author describes the embryologic development of the eye and shows how these lesions may be formed. He points out that belief in purely mechanical factors in morphogenesis, such as for example the theory that invagination of the primary optic vesicle is induced by pressure from the developing anlage of the lens, must be abandoned. All the processes of development result from imminent directives of growth which are controlled by the hereditary constitution of the developing individual.

This leads Strebel to some remarks on his convictions about the hereditary origin of myopia. The extreme degrees which are associated with degenerative changes at the posterior pole of the eyeball are usually fully developed in earliest childhood, and he classifies them as stable. The individuals with the more common and more moderate degree of myopia, which he classifies as labile or dynamic, also inherit the tendency toward nearsightedness, but environmental factors play some part in the amount of myopia which develops. Strebel himself has demonstrated the association of disturbances in calcium metabolism with the development of myopia, and there is evidence that the type of individual that is apt to develop myopia has also a poor development of connective tissues. Pressure of the lids may play a part and so does the tension of the extraocular muscles. Strebel has demonstrated that the asymmetries of the globe are directly proportional to frequency of use of the muscle which lies in the area of deformation. (9 figures, including 3 color plates.)

Sysi, R. Investigation as to the effect

of vitamin B₁ on accommodation. Klin. M. f. Augenh., 1941, v. 107, Sept., pp. 301-306.

A preliminary report on experiments with 26 normal emmetropic individuals, between 26 and 69 years of age, whose range of accommodation was tested before and after injection of vitamin B₁. In younger persons as well as those over 61 years practically no effect was observed. In some persons of pre-presbyopic and presbyopic age a definite increase in range of accommodation could be found within a half hour after injection; and this increase lasted for 24 hours or longer. The effect disappeared gradually within four or five days. The refraction never showed any change during the period of observation. The mechanism is not yet completely explored. (One table, references.) F. Nelson.

Trendelenburg, Wilhelm. Inheritance in a case of anomalous color sense in one and normal color sense in the other eye. Klin. M. f. Augenh., 1941, v. 107, Sept., pp. 280-293.

The patient, a physician, had been examined by Kries more than twenty years previously, when his left eye had been found normal as to color sense, the right deuteranomalous. The unilateral anomaly was congenital. The same condition was found in 1941. No color-sense abnormalities were known in the ascendants. The man's daughter, 17 years of age, was found deuteranomalous in both eyes; and the son, six years old, deuteranopic in both eyes. The children's mother was phenotypically normal but was, of course, a transmitter of deuteranopia. (Bibliography.) F. Nelson.

Tron, E. Posterior principal plane of the optical system of the eye and

significance for refraction Arch. of Ophth., 1935, v. 34, Aug., pp. 107-111.

Measurements were made on 275 eyes to determine the significance of the position of the posterior principal plane on refraction. The radius of corneal curvature was measured with the Javal ophthalmometer. The radii of curvature of the surfaces of the lens, the depth of the anterior chamber and the thickness of the lens were measured with the Tscherning ophthalmometer. The position of the posterior focus and the length of axis were calculated on the basis of the data obtained from these determinations after refraction under atropine cycloplegia.

It was found that the position of the posterior principal plane varied within the limits of 1.06 to 2.51 mm. The average value was 1.63 mm. The position of the posterior principal plane is the same with various types of refraction. The greater the refractive power of the eye and of the lens, the farther the posterior principal plane is situated from the cornea. The length of axis has no effect on the position of the posterior principal plane. A special kind of ametropia was noted in 1.85 percent of the eyes, in which a refractive anomaly resulted from the position of the posterior principal plane in the optical system.

Changes in the position of the posterior principal plane are of no importance for the genesis of anisometropia and changes in both eyes are considerable in isometropia.

John C. Long.

Weber, Ernst. Heredity of refraction on the basis of studies in twins. Klin. M. f. Augenh., 1941, v. 107, Dec., pp. 574-577.

Weber reports the refraction of five pairs of twins, each pair of which certainly or very probably arose from a single ovum. The results confirm Steiger's teachings. Refractive state is a manifestation of growth-regulating factors. Twins with concordant anisometropia particularly suggest that refraction is determined by the constitution of the germ plasm, and not mechanistically. (2 illustrations.)

OCULAR MOVEMENTS

Adler, F. H. Effect of anoxia on heterophoria and its analogy with convergent concomitant squint. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 227-232.

In a previous paper by the author, the existing knowledge of the voluntary and motor mechanisms controlling ocular movements was summarized. The chief source of reflex tone is the visual fixation reflex. All of the other sources of tone, together with the visual fixation reflex, suffice to keep the eyes in alinement with each other. When the visual fixation reflex is artificially eliminated by one means or another and the position of the eyes is measured, one is determining the effect

of all these other sources of tone working together. This is spoken of as the measurement of the muscle balance. One must conclude therefore that heterophoria is an indication that the remaining reflex sources of ocular muscle tone have failed to keep the eyes in perfect alinement when the fusional mechanism is eliminated.

It has been known for some time that under the influence of alcohol there develops an increasing esophoria, which, with increasing loss of the fusional fixation reflex becomes an esotropia. A similar development of esophoria has been found to occur from the effect of anoxia by Velhagen. Since this was contrary to what Berens and Wilmer had previously reported, Adler repeated these experiments.

The experiments reported here were made in a low-pressure chamber. From the data collected he concludes that during the lack of oxygen, there is a shift of the range of fusion toward the convergent position. The range itself shows little change in the normal subject who has a normal range of fusion. If the range is abnormally small to begin with, it may be wiped out altogether, and homonymous diplopia may develop.

The development of exophoria under the influence of alcohol and anoxia is due either to an increase in convergence tone or to a diminution of divergence tone. There is no evidence in the literature or in the data presented here which points strongly to either assumption.

The esophoria produced by alcohol and anoxia, which may even become esotropia, may not be the same as that which occurs in early childhood and which leads to concomitant squint, but there is enough similarity in the two

conditions to suggest study of squint from this point of view. Both are caused by some interference with a supranuclear mechanism.

Gillan, R. U. An analysis of one hundred cases of strabismus treated orthoptically. Brit. Jour. Ophth., 1945, v. 29, Aug., pp. 420-428.

The study of 100 cases of strabismus was undertaken to compare the deviation and the degree of binocular vision present at the conclusion of treatment with that present at the commencement.

Sixty-three cases were treated by orthoptic treatment only. Twenty-three of these became perfectly straight. The original deviations were from 3° to 25° —average 10° . Twenty-five became almost straight, the final deviation being less than 5° . In these cases the original deviations were from 3° to 20° —average 10.35° . Fifteen did not become straight, the final deviation being over 5° . In these cases, the original deviations were from 10° to 30° —average 16.8° . The percentage of

complete success in this group of deviations is 36.5 percent.

Thirty-six of the 63 cases developed good binocular and stereoscopic vision as tested by the synoptophore, cover testing, and Worth's lights. All of these commenced with simultaneous perception and fusion. Seven cases developed fair stereoscopic vision and 20 developed no stereoscopic vision. Of the 23 cases which became straight, all commenced with simultaneous perception and fusion. It would appear, therefore, that the development of orthopsis by means of orthoptic treatment alone depends to a large extent upon the degree of binocular vision present at the commencement of treatment as well as upon the degree of deviation. The possession of simultaneous perception and fusion is an essential prerequisite for success.

Thirty-seven cases were treated by orthoptic treatment plus operation. Six of these became perfectly straight, the average deviations being from 20° - 35° —average 29° . Seventeen became nearly straight, the final deviation being 5° or less, the original deviations being from 15° to 60° —average 33.1° . Fourteen cases did not become straight, the final deviations being over 5° , average original deviation 35.8° .

Of the 100 cases, 25 became fully straight and fully stereoscopic, 20 became almost straight and fully stereoscopic, 26 became straight or almost straight without becoming fully stereoscopic, and 29 became neither straight nor stereoscopic.

In order to meet the criticism that perhaps some of the cases might have become straight without treatment, the results were checked against a series of comparable cases which had no treatment except the wearing of

glasses. In a series of 50 cases under observation for an average of nine months, there was not one in which orthopsis or stereoscopic vision was developed.

Those cases having simultaneous perception and fusion to commence with and developing good stereoscopic vision form the majority of cases becoming straight. It would appear, therefore, that the absence or failure of stereoscopic vision is the chief factor in the causation of concomitant strabismus. Edna M. Reynolds.

Leoz, G. Perverse phenomenon of Bell or of Fuchs. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 539-547.

In this case the eyes turned downward instead of upward on forcibly opening the lids. The author discusses the nervous mechanism of the normal Bell's phenomenon.

J. Wesley McKinney.

López Domínguez, Bernabé. Functional and cosmetic results of the treatment of convergent strabismus. *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 842.

The surgical pattern followed by López consists of tenotomy of the internus of the nonfixating eye, followed, if inadequate, by tenotomy on the other eye. Slight over- or undercorrections are left alone. Marked undercorrection is dealt with by advancement of the externus of the nonfixating eye. The author has not had a case which required bilateral advancement in addition to bilateral tenotomy. He uses no bandage after tenotomy, but atropine is instilled to abolish accommodation. He does not regard tenotomy as a simple procedure, and reports one case in which severe retrobulbar hemorrhage

compressed the optic nerve and produced blindness of the fixating eye. He finds the result of tenotomy better if the conjunctival incision is horizontal instead of concentric with the limbus. In some cases vertical deviation followed tenotomy. This should be corrected with lenses, lest it interfere with development of binocular vision.

Ray K. Daily.

Marín Amat, M. Inverse Bell's sign. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, July-Aug., pp. 534-538.

A case is reported wherein the eyes turned directly downward on attempted closure of the lids and in sleep, instead of upward as in the true Bell's phenomenon. A 45-year-old man had a cicatricial ectropion of the left upper lid of five years' duration. The lid border had been drawn up to the eyebrow as a result of an old fistula of the frontal sinus at the orbital rim. There was lagophthalmic keratitis of the upper cornea. In forcible closure of the eyes (impossible of accomplishment in the left eye) and in sleep, the eyes rotated downward so that the corneas were completely hidden by the lower lids. The phenomenon is explained as at first a voluntary protective movement and later an educated reflex pattern. (3 figures, references.)

J. Wesley McKinney.

Moron y Ruiz, José. A controlled suture for muscular advancement. *Arch. de la Soc. Hisp.-Amer.*, 1944, v. 4, Sept.-Oct., p. 839.

For traumatic diplopia due to paralysis of the externus, the author places a loop over each end of the muscle including the conjunctiva, passes the suture through the episclera close to the limbus, and tightens it slowly as the patient fixates a line; when the patient

states that he has no diplopia the suture is tied. In strabismus this suture is inserted, a tenotomy of the antagonist is performed, and the suture tied when the visual lines appear parallel. The writer claims for this suture the advantages of the Lagleyze and Worth sutures, it being as easy to regulate as is the Lagleyze suture, and having as firm a hold on the muscle as the Worth suture. (Illustration.)

Ray K. Daily.

Muck, O. The cause of miners' nystagmus and suggestions for further research in this field. *Klin. M. f. Augenh.*, 1942, v. 108, Jan.-Feb., p. 67.

The cause of nystagmus of miners has not yet been satisfactorily explained. The inadequate illumination, pathologic conditions in the labyrinth, the "unnatural" gaze upwards in narrow shafts as well as the intoxicating influence of various gases in poorly ventilated coal mines are factors which have been suggested by various authors. The inhaling of certain gases (ether, chloroform) exerts a temporary inhibitory influence on different types of nystagmus. Temporary disappearance of central nystagmus has been seen after consumption of alcohol. On the other hand spontaneous nystagmus can be produced by alcohol and veronal. Among the gases most frequently found in coal mines methane may have something to do with the occurrence of miners' nystagmus. However, lack of oxygen sometimes makes nystagmus disappear, and in other instances a miner's nystagmus that had been present underground only reappeared above ground after compression of both jugular veins. Nystagmus can be inhibited by the same agents that are able to induce it. Muck's opinion is that the methods of examination used

by nerve, eye, and ear specialists, which hitherto have been quite different, should be standardized and made uniform in order to establish comparable conditions. He proposes that young men who intend to become coal miners should submit to preliminary tests, wherein they inhale air mixtures from ill-ventilated coal mines in order to find out whether such mixtures are intoxicating to these individuals. (References.)

F. Nelson.

Ohm, J. Optokinetic nystagmus in very dim illumination. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 187-195.

The author reminds the reader that optokinetic nystagmus is a function of the peripheral retina. Since the nystagmus can be inhibited by placing minute objects that stimulate central fixation before the revolving drum, this procedure may be used as an objective measure of visual acuity. Optokinetic nystagmus induced in dim light, the intensity of which can be measured, may be used as a means of measuring a patient's light sense objectively. He describes the necessary modifications of his older armamentarium, and gives evidence that the method is reliable. (7 graphs, references.)

CONJUNCTIVA

Baraff, A. A. **Gonorrheal ophthalmia neonatorum.** Illinois Med. Jour., 1945, v. 87, May, p. 249.

A case of gonorrheal ophthalmia neonatorum is presented which terminated in blindness and which, probably, could have been avoided if the proper therapeutic measures had been instituted. The case, in spite of the state laws, has never been reported to the local health authorities.

R. Grunfeld.

Bernasconi, S. F. **Gonococcic conjunctivitis treated locally with penicillin.** Arch. Chilenos de Oft., 1945, v. 1, Jan.-Feb., pp. 18-19.

The author reports his rapidly successful treatment of bilateral ophthalmia neonatorum in an infant aged nine days. A solution containing 1,000 Oxford units per c.c. was instilled every hour, and the bacteriologic condition was recorded every two hours. In 7½ hours palpebral edema had disappeared and the secretion had become scanty. In 24 hours there was no secretion and the conjunctiva was normal in appearance.

W. H. Crisp.

Bland, J. O. W. **The etiology of trachoma.** Brit. Jour. Ophth., 1945, v. 29, Aug., pp. 407-420.

The two theories of the etiology of trachoma—the virus theory and the rickettsial theory—are not incompatible. Evidence is presented which proves that trachoma is a specific infectious disease, not caused by any cultivable bacterium, but by a filter-

passing agent which is identical with the elementary and initial bodies found in the Prowazek-Halberstaedter inclusions and bearing a close natural relationship to the viruses of inclusion conjunctivitis, lymphogranuloma inguinale, and psittacosis.

The view is advanced that these agents stand in an intermediate position between the rickettsia and the large viruses and may form a biologic link between them. They are classified by the author as basophilic viruses. (Bibliography.)

In the course of a few months the author observed 12 cases of typical Parinaud's syndrome in people working with a flock of chickens afflicted with chicken pest. A veterinarian identified the disease as infectious laryngotracheitis.

F. Herbert Haessler.

Gersh, I., and Reich, N. E. Arthritis, urethritis, and conjunctivitis (Reiter's disease). *Urologic and Cutaneous Rev.*, 1945, Aug., p. 472.

The authors report a case of Reiter's disease exhibiting the triad arthritis, urethritis, and conjunctivitis. Physical examination of a soldier, 19 years of age, revealed bilateral conjunctivitis with a crusted yellow discharge, marked

effusion into both knee joints with moderate pain and stiffness, and a profuse urethral discharge. The urethral meatus was red and pouting. Smears and cultures of the urethral discharge revealed nonhemolytic *Staphylococcus albus*. The conjunctival discharge contained nonhemolytic *Staphylococcus aureus*. The joint fluids were free from organisms. Injection of the urethral discharge into a male guinea pig was followed by the development of a purulent urethritis but by neither eye nor joint involvement. The organism of this urethral discharge was proved to be nonhemolytic *Staphylococcus aureus*, and the authors consider this organism to be the etiology of Reiter's disease.

Neither sulphathiazole nor penicillin proved to be therapeutically effective.

Jacobson, M., and Levin, N. Epidemic keratoconjunctivitis cured through the combination of penicillin and sulfasuxidene. *New York State Jour. Med.*, 1945, v. 45, Sept. 15, p. 1990. (See Section 6, Cornea and sclera.)

Lijó Pavía, J. Burn of the cornea and conjunctiva. How to prevent symblepharon. *Rev. Oto-Neuro-Oft.*, 1944, v. 19, Nov.-Dec., pp. 159-171.

The paper is prefaced by a very complete discussion of the views of other writers. The substances most commonly causing corneal and scleral burns are lime, ammonia, acids, and hot or molten metals. The degree of reaction depends on the severity of the burn. The results from this type of burn are hyperemia and edema, cauterization, necrosis, granulation, and finally cicatrization with adhesions.

A young adult suffered a severe

burn of the lids, cornea, and conjunctiva, from flaming naphtha. After immediate and abundant irrigation and local anesthesia, a mold of surgical "Korina" (amidoazotoluol) at a temperature of 45° to 47°C., was placed in the eye over the cornea, extending to both fornices. Atropine ointment was added. After 11 to 13 days sufficient healing and epithelization had occurred to allow removal of the mold. No permanent adhesions formed. Vision remained at 0.3. The author prefers this mold and atropine ointment to mucous graft, interposition of rabbit peritoneum, or contact lens. (7 illustrations, references.) Edward Saskin.

Lucas, R., and Weiss, H. **Gonorrheal syndrome without gonorrhea.** *Arch. of Ophth.*, 1945, v. 34, Aug., pp. 97-98.

The triad of urethritis, conjunctivitis, and arthritis, occurring in this order, in the absence of a gonococcic etiology, is known as Reiter's disease. The anterior and posterior urethra are involved and often the bladder. The symptoms are so similar to those of gonorrhea that suspicion of the gonococcus is difficult to dispel. An acute purulent conjunctivitis is a constant finding. A tendency to spontaneous recovery without corneal ulceration is the rule. Keratitis and iritis often occur. Chronic arthritis is usually the cause of the severest complaint. The arthritis involves more than one joint and clears up in from one to five months without ankylosis. Cutaneous lesions may be simple erythemas, urticarial or erythema-nodosum-like eruptions, hemorrhagic and vesicular eruptions or hyperkeratitic lesions. The disease cannot be distinguished from gonorrhea clinically. Failure to demonstrate the gonococcus is the differentiating

feature. The condition does not respond to penicillin or sulfadiazine nor to any other known specific remedy. Complete recovery is the rule.

The authors report a case of Reiter's disease in a 29-year-old man developing 10 days after exposure. An acute urethritis developed first and was followed in three weeks by a severe purulent conjunctivitis. Arthritis of the toes, fingers, wrist, heel, and knee developed. Coincident with the arthritis a cluster of superficial vesicles were noted in the center of each cornea. Iritis with keratitic precipitates developed in each eye. Hemorrhagic vesicular cutaneous lesions appeared. Within two months all symptoms had gone. Administration of sulfathiazole and penicillin had no positive effect on the disease. Repeated conjunctival and urethral smears, as well as urethral, blood, and synovial-fluid cultures were all negative for the gonococcus.

John C. Long.

Paez Allende, Francisco. **Concerning a case of diffuse neurofibromatosis of the bulbar conjunctiva (Recklinghausen's disease) with skeletal and cutaneous manifestations, asymmetry of the body and intracranial involvement.** *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Sept., pp. 438-453. (See *Amer. Jour. Ophth.*, 1945, v. 28, Aug., p. 933.)

Poleff, L. **The real value of treatment by sulfonamides in trachoma.** *Ophthalmologica*, 1943, v. 105, March-April, pp. 156-174.

After reviewing the literature on the subject the author expresses the opinion that sulfanilamide acts in trachoma through bacteriostasis with subsequent destruction of the virus by phagocytosis. The drug has no resorbing

effect on the follicles and is, therefore, not a cure-all for trachoma. While it is of great value in clearing the infection and the corneal complications, it should be used only in conjunction with local therapy. Based on the observation of 1,050 cases of trachoma in Morocco the author recommends vigorous massage treatment of the conjunctiva with glass or silver stick for several months, eventually preceded by an expression of the follicles. During the same time sulfonamides are given by mouth. It is only in very early cases with little formation of follicles that sulfonamides alone may be sufficient. In the fully developed cases the combined treatment is the method of choice and will arrest the average case in three months. Sulfanilamide effects a sterilization of the infection and is the best precaution against recurrences. (Bibliography) Max Hirschfelder.

Rössler, F. The treatment of trachoma with cold applications. *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 365.

Davids has reported that application of snow or ice to the trachomatous conjunctiva has a healing influence on the inflammatory process but Rössler had published the results of such experiments carried out in 1912. They were not encouraging. Though it is well known that cold applications reduce the acute irritation of a fresh case of trachoma, this does not mean that such applications can heal the disease. F. Nelson.

Schmelzer, H. Allergic conjunctivitis and pervitin. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 179-184.

In two patients with characteristic allergic conjunctivitis in the course of hay fever, a variety of the usual

symptomatic remedies failed to give relief. There was an immediate favorable response to pervitin, a drug whose structural formula resembles benzedrine and ephedrine. (References.)

F. Herbert Haessler.

Sorsby, Arnold. Local penicillin for ophthalmia neonatorum. *Brit. Med. Jour.*, 1945, June 30, p. 903.

Results of local penicillin therapy in 38 cases of ophthalmia neonatorum are described. The drug was used in a concentration of 2,500 units per c.c. Thirteen cases were treated with instillations at intervals of one hour for six hours, then of two hours for 24 hours, and subsequently of three hours. All cases responded well with clinical cures in from 4 to 60 hours. Twenty-five cases were treated with instillations every five minutes until pus formation ceased, then every half hour until the eye was dry, every hour for 12 hours and every two hours for 24 hours. In two cases the response was poor but gratifying in all the others; clinical cure occurred in 38 hours at the longest and 25 minutes at the best with an average of ten hours. Infections with gonococcus, staphylococcus, streptococcus, Morax-Axenfeld and diphtheroid bacillus and inclusion blennorrhea were treated. The type or severity of the infection had no bearing upon the results. During this regimen no irrigations after an initial one are necessary as pus formation ceases within one-half to three hours. No untoward reaction to the penicillin was noted.

CORNEA AND SCLERA

Atkinson, W. S. Interstitial keratitis treated with subconjunctival injections of penicillin. *Arch. of Ophth.*, 1945, v. 34, Sept., p. 233.

The author reports the case of a 27-year-old man who developed interstitial keratitis in spite of antiluetic treatment. He was given seven daily subconjunctival injections of 0.5 c.c. of sodium penicillin (1,000 Oxford units of penicillin per c.c.) The signs and symptoms subsided rapidly. Two months later when the patient was last seen, the vision was 20/15 and the eye was quiet. R. W. Danielson.

Bashoff, P. H. The results of corneal transplantation and plastic operations. *South African Med. Jour.*, 1945, v. 19, June 23, p. 209.

The author describes 30 cases of keratoplasty. In the first nine cases he made transplants according to the methods of Filatov and Weiner with formalin-treated tissue. Results obtained were negligible to bad. In the next 17 cases 2-mm. auto transplants were taken from the clear portion of the recipient's corneas after the method of Morax. Results were good in 13 of the 17 cases. The reaction of the cornea to the graft of its own tissue was very slight. The last four patients had keratoconus and were treated according to the Webster Fox operation. An elliptical segment was removed from the cornea just below the pupil and the edges approximated by sutures. The cone was thus flattened and any apex scar moved below the pupil; the resulting irregularity of the whole cornea was obviated by the contact lens subsequently fitted. The final results

in these cases were quite satisfactory. Morris Kaplan.

Bischler, V. The different forms of metallic impregnation of the cornea. *Arch. d'Ophth.*, 1941-42, no. 3-4, v. 4, p. 114.

The case of a silversmith is presented. The right cornea showed a ring of the Kayser-Fleischer type, the left cornea an identical change except for the fact that it involved the entire extent of Descemet's membrane. An unusual feature of the case was that dark adaptation was markedly diminished. Pseudosclerosis and impregnation of the cornea with salts of gold and copper could be excluded and a diagnosis of professional argyrosis of the cornea established. The biomicroscopic appearance is given in detail, but the accompanying illustrations are poorly reproduced. A complete review of the subject of metallic impregnation of the cornea precedes the case report.

This additional information should be read in conjunction with a paper published by the authors in the *Arch. of Ophth.*, 1945, v. 33, Feb., p. 106. For abstract see *Amer. Jour. Ophth.*, 1945, v. 28, Aug., p. 935.

Edeskuty, Otto. Ichthyosis of the cornea. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 170-176.

Congenital ichthyosis is rarely complicated by a corneal lesion. The author describes a patient with congenital ichthyosis in whom there were corneal lesions which he believes to be manifestations of the patient's congenital

defect. He found descriptions of four similar cases in the literature. The corneal lesion consists of subepithelial opacities in the superficial layers of the central area of the cornea. The opacity is nodular; there are proliferation of blood vessels and great photophobia without objective signs of irritation. An accompanying conjunctival inflammation with papillary hypertrophy may be an essential part of the disturbance. The lesion is differentiated from Groenow's nodular corneal dystrophy by the absence of corneal opacity in the deeper layers. The confluence of the opacity suggests a disciform lesion. (References.) F. Herbert Haessler.

Feigenbaum, A., Michaelson, I. C., and Kornblüth, W. Epidemic keratoconjunctivitis in the Middle East. *Brit. Jour. Ophth.*, 1945, v. 29, Aug., pp. 389-406.

Three hundred and eighty one cases of epidemic keratoconjunctivitis occurring between 1938 and 1944 are reported. The epidemic occurred at the beginning of the rainy season. Trauma was found to play a considerable role in the etiology of the disease.

The incubation period appeared to be between five and fourteen days. The incidence of the disease was not affected by age, sex, or social class. No recurrence was observed, but there were exacerbations when the disease was protracted.

The subjective symptoms consisted of prickling, itching, and sensation of a foreign body in the eye, later followed by slightly blurred vision. The objective findings were lacrimation, swelling of the lids, pseudoptosis, a typical glistening of the conjunctiva (cellophane-surface appearance), marked swellings of the conjunctiva of the

lower lid which were sometimes cocks-comblike, swellings of the plica semilunaris and caruncle, and painful swelling of the preauricular gland, often accompanied by swelling of the submaxillary gland. Especially notable was a delicate fibrinous, threadlike secretion, such as is commonly found in spring catarrh. Conjunctival smears and cultures were negative.

The condition began bilaterally in 50 percent of the cases.

The corneal lesions were found to be of three different types: (1) ill-defined subepithelial dots, (2) superficial epithelial infiltrates some of which were vesicular and some of which stained, (3) disciform keratitis. Corneal changes were found in 60 percent of the cases and appeared from seven to seventeen days after the conjunctival changes.

The conjunctival changes gradually diminished after a few weeks, while the corneal complications persisted from a month to two and one-half years.

Energetic treatment with silver and copper salts was found to aggravate the condition. The best treatment was frequent instillation of concentrated adrenalin solution (1: 4,000) and douching with cold water. After the complete disappearance of the conjunctival changes, 2-percent yellow oxide of mercury ointment with 5-percent dionin were useful for the corneal infiltrations. Sulfonamide, locally or by mouth, did not help the condition and penicillin had no effect whatsoever. In a few cases of disciform keratitis, intravenous injection of 1 to 3 c.c. of a 10-percent solution of sodium iodide brought about rapid improvement.

Experiments with rabbits confirmed the specific nature of the causal agent.

Tissue cultures and filtration experiments showed this to be a filtrable virus. Mice could not be infected.

Immune bodies were shown to be present in the blood of convalescent human beings.

Histologic examination of human conjunctival tissue showed flattening of the epithelium, marked capillary dilatation and edema in the subepithelial tissue, and infiltration with lymphocytes and large mononuclear cells with multiple mitoses. In the chronic cases, there was marked papillary hypertrophy. (4 graphs, 3 photographs, 11 microphotographs, references.) Edna M. Reynolds.

Garibay, C., and Cortés Zavala, A. **Keratitis nodosa due to caterpillar hair.** *Anales Argentinos Oft.*, 1944, v. 5, Oct.-Nov.-Dec., pp. 136-138.

A young adult male felt a sharp pain in his right eye and brushed a "hairy worm" from his lids. For two months he was treated by a general physician before consulting an oculist. At this time he had edema of the upper lid, photophobia, lacrimation, conjunctival congestion, superficial punctate corneal lesions, and iritis. Slitlamp examination revealed nodular infiltration of the cornea with a fine reddish hair occupying the center of each nodule. Following extraction of the caterpillar hairs the patient was much relieved. However, intraocular infection supervened, due either to corneal perforations by the hairs, or some venom thereof. At last examination the eye was atrophic and enucleation seemed advisable. Edward Saskin.

Harley, R. D., and Kaiser, R. F. **Keratitis associated with malaria.** *Amer. Jour. of Ophthal.*, 1945, v. 28, Dec., pp. 1309-1312.

Jancke, G. The uniformity of epidemic forms of keratoconjunctivitis described under different terms from 1889-1941. (*Keratitis punctata, nummularis, maculosa epidemica*, etc.) *Klin. M. f. Augenh.*, 1942, v. 108, Jan.-Feb., p. 39.

First described by Fuchs during an epidemic in Vienna in the years 1885 to 1890 under the name *keratitis punctata superficialis*, apparently the same or a very similar disease was reported during the same epidemic by Stellwag, Reuss, and Adler who named it *keratitis nummularis, keratitis maculosa*, and *keratitis subepithelialis centralis*, respectively. Later other names were added. Jancke believes that these seemingly different diseases are manifestations of the same disease, an epidemic keratoconjunctivitis which spreads in waves at varying intervals over large areas. For all these related types he proposes the uniform term *keratoconjunctivitis nummularis epidemica*. (Bibliography) F. Nelson.

Jacobson, M., and Levin, N. **Epidemic keratoconjunctivitis cured through the combination of penicillin and sulfasuxidine.** *New York State Jour. Med.*, 1945, v. 45, Sept. 15, p. 1990.

The authors publish their observations of a patient who had epidemic keratoconjunctivitis for three months. He had marked hyperemia of the palpebral and bulbar conjunctivas, tearing, photophobia, and opacities of the cornea. The patient showed remarkably fast response to combined sulfasuxidine and penicillin. Theodore M. Shapira.

Purtscher, Ernst. Crystalline deposits in the cornea after lime burn. *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 357.

The author reports one case of severe lime burn which resulted in complete destruction of the bulbar conjunctiva and corneal epithelium and almost complete degeneration of Bowman's membrane. After 10 days numerous chalky-white concretions of various sizes appeared in the corneal parenchyma of which the smaller ones were spherical, and the larger ones irregularly polygonal or quadrangular. Five weeks after the accident the perforation of the cornea increasing pain, and loss of all function led to enucleation. Histologic examination revealed that the corneal lamellae were separated by hyaline bodies which were stained faintly pink with eosin and hematoxylin. It is assumed that these formations were organic calcium compounds. (1 drawing, 1 microphotograph, references.)

F. Nelson.

Reca, Arturo. Neuroparalytic keratitis. *Anales Argentinos de Oft.*, 1944, v. 5, July-Aug.-Sept., pp. 90-91.

The author discusses a case of surgical destruction of the Gasserian ganglion performed for the relief of a trigeminal neuralgia. Keratitis developed about two months after operation, with typical trophic and inflammatory reaction. Treatment consisted of warm compresses, atropine, dionine, sulfa solutions, and protein injections. No statement is made as to relief or recovery.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Arjona, J. Expulsive hemorrhage. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Nov.-Dec., p. 1031.

Arjona reviews the literature and illustrates with microphotographs the vascular lesions in his own case. These show an inflammatory lymphocytic infiltration around the choroidal vessels. He concludes that the basic cause of an expulsive hemorrhage is an inflammatory or arteriosclerotic disease of the blood vessels, particularly of the ciliary vessels. The sclerosis may be a part of a general arteriosclerosis, or a purely local lesion; or it may be a sclerosis due to an undiagnosed glaucoma which leads to a vascular fragility and inability to withstand the increased vascular pressure which comes with the sudden drop of the intraocular pressure when the eyeball is opened. As a prophylactic measure the author urges careful examination for latent glaucomatous processes through provocative tests and tension curves; if discovered they should be controlled by preliminary iridectomy or miotics. When general hypertension cannot be reduced by medication, a venesection immediately before the operation is advised. After the loss of one eye from an expulsive

hemorrhage the operation on the other eye should be preceded by the administration of calcium chloride, coagulants, and vitamins C and K. The cataract extraction in such cases should be extracapsular, leaving the posterior capsule with its ciliary attachment intact. After an expulsive hemorrhage has occurred early enucleation will spare the patient unnecessary pain and the hazard of sympathetic ophthalmia. Filatov's proposal of a prophylactic and curative scleral trepanation at the equator is mentioned; the author had no experience with it, but it appears to him that it is impractical and ineffective. (3 illustrations.) Ray K. Daily.

Appel, Hans. Bilateral hypochromia (Fuchs's heterochromia) and signs of status dysraphicus. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 166-169.

Appel describes the eyes of a patient in whom there was a hypochromic iris complicated by postcorneal deposits, turbid aqueous, and cataract in each eye, but without synechiae. Fuchs had already mentioned that complicated heterochromia might occur in both eyes but never observed a case. Since then eight observations have been published. Appel describes another case of bilateral hypochromia observed at the Freiberg Clinic earlier. The heterochromia was complicated by glaucoma, which is not uncommon. The patient also had several manifestations of status dysraphicus, which are considered signs of early syringomyelia. (References.) F. Herbert Haessler.

Castañé Decoud, D. D'A. de. Choroidal melanomas. *Anales Argentinos de Oft.*, 1944, v. 5, Oct.-Nov.-Dec., pp. 123-135.

The paper presents an evaluation of the study of 17 cases of choroidal

melanoma in the past ten years. Eleven cases are discussed, with macro- and micropathology described. A well-developed table of conclusions is included. (1) This condition represents but 0.05 percent of all eye cases; (2) it occurs mainly in the fifth to seventh decades of life; (3) it is most commonly situated at the equator and anterior choroidal segment; (4) patients have lived for from two to ten years after enucleation; (5) the tumor is round, circumscribed, enveloped by melanophores, and has an almost true membrane; and (6) the most common cellular types of tumor are roundcell and fusiformcell, with an occasional mixed-cell. (11 illustrations, 1 table.)

Edward Saskin.

Goedbloed, J. Mode of inheritance in choroideremia. *Ophthalmologica*, 1942, v. 104, Dec., pp. 308-315.

Three cases of choroideremia within the same family are described. From the mode of inheritance in this family as well as from the reports in the literature the author concludes that the condition shows an intermediate gonosomal heredity. Men who are affected always show a true choroideremia. Their sons are normal, but their daughters will have a pepper and salt fundus.

Max Hirschfelder.

Hudelo, Guillaumat, and Maussion. Traumatic arciform choroiditis. *Arch. d'Ophth.*, 1945, v. 5, no. 1, p. 44.

Four cases of severe contusion of the globe in which choroidal tears resulted are reported. All four cases had in common an absence of hemorrhage and an apparent late development of the lesion. In the first case it was not possible to make a definite diagnosis until two months after the traumatism, while in the second the typical ophthal-

moscopic picture developed at the time of the second examination. In the third case the fundus appeared normal until the sixth day and the tear became visible four days later. The fourth case had an apparently normal fundus until two weeks after the injury when a typical juxtapapillary tear with degeneration of the macula was seen.

After a review of 33 cases reported in the literature the authors conclude that the lesion is not an actual tear but a traumatic necrosis of the choroid. In support of this opinion they note the late appearance of the so-called tear, the absence of the hemorrhage which would be inevitable if an actual rupture occurred, and the usual absence of edema.

Phillips Thygeson.

Saggesse, D. A., and Decoud, A. C. Conglomerate tuberculoma of the choroid. *Anales Argentinos de Oft.*, 1944, v. 5, July-Aug.-Sept., pp. 84-89.

In a child two and a half years of age a diagnosis of typical glioma of the left eye was made at the first examination. A yellow-white tumefaction in the vitreous cavity extended from behind the lens to the fundus. The right eye was normal. Enucleation was advised, but a month elapsed before operation. During this time the vitreous mass had become somewhat smaller and several scleral plaques or nodules had appeared. The Mantoux reaction was strongly positive.

After enucleation microscopic examination revealed typical giant and epithelioid cells, lymphocytic infiltration, and several adjacent similar choroidal follicles. Final diagnosis was tuberculoma.

Differential diagnosis requires careful ophthalmoscopy, history, serologic and radiologic study, and frequent re-examinations. The treatment of ad-

vanced cases is enucleation, provided the sclera is intact. (Bibliography.)

Edward Saskin.

Stock, W. Chronic uveitis, its etiology and treatment. *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 257.

Since Stock produced a typical nodular iritis, iridocyclitis and choroiditis in animals by introducing tubercle bacilli into the blood stream, it has been recognized that a certain number of cases of chronic uveitis in men are tuberculous in origin. However, Stock does not think that all cases of nodular chronic uveitis are tuberculous since any type of chronic infection that is spread through the blood stream can produce nodules. The clinical course of a chronic uveitis is not characteristic for one particular infection. The only data that give a certain amount of safety in diagnosing chronic uveitis are a tuberculin test and the effect of subsequent treatment. A definite focal reaction in the affected eye during the time of general reaction to one milligram of old tuberculin injected intracutaneously indicates that the eye is also suffering from an active tuberculous process. A thorough general examination of the patient is essential including fluoroscopy, sedimentation rate, dental examination and Wassermann reaction. If the patient has a normal temperature for three consecutive days the tuberculin test is made routinely. Though many patients have a positive reaction locally, a focal reaction in the eye is seen in only about 20 percent of these cases. In the latter cases X-ray treatment is administered immediately (20 percent s.e.d. = 100 r.). If after the X-ray treatment a slight ciliary injection, cloudiness of the chamber fluid and pains occur the prognosis is good. Some cases heal completely after one

treatment. If the treatment is followed by improvement but not complete recovery a second dose is given after six weeks. This interval is chosen because a delayed reaction sometimes occurs after four weeks. Stock has never seen any detrimental effect from the X-ray treatment. In more than 1,000 patients there was not a single case of roentgen cataract and often there was a definite decrease of the tension in eyes with secondary glaucoma. All cases of chronic uveitis which react this way are tuberculous. When the tuberculin reaction is negative the patient is given 10 c.c. of atophanyl intravenously daily. When the lesion responds to this treatment it is regarded as rheumatic. Atophanyl is also very helpful in sympathetic ophthalmia. Local treatment is given as usual.

There remain some patients who respond neither to irradiation nor to atophanyl but relatively well to eubasin or cibazol. In these cases one of the cocci is probably the etiologic agent. Stock does not favor sending patients to mountain sanatoria for climatic treatment. Most of his patients with severe chronic uveitis come from the Black Forest and relatively few from the northern plains. He prefers to send such patients to the sea shore.

GLAUCOMA AND OCULAR TENSION

Bloomfield, S., and Lambert, R. K. The lability of ocular tension. Arch. of Ophth., 1945, v. 34, Aug. pp. 83-96.

Detailed tests were conducted to determine the effect of sudden increase in arterial pressure on the intraocular pressure in both normal and glaucomatous eyes. The increase in vascular pressure was produced by immersion of the hand in cold water. The vascular and intraocular-pressure response to cervical compression was also studied. The intraocular-pressure and vascular-pressure response to simultaneous cervical compression and cold immersion was also tested. The changes in intraocular pressure encountered were not great but were of significance.

The authors concluded that the normal maintenance of intraocular pressure within an optimum range suggests the presence of a regulatory mechanism. Dysfunction of such a hemostatic

system may result in abnormal lability of intraocular pressure and may eventuate in chronic simple glaucoma. The method of cold stimulus plus cervical compression to test lability may prove of value for the earlier diagnosis of chronic simple glaucoma and the evaluation of therapeutic measures for that disease.

John C. Long.

Brausewetter-Koppner, G. Comparison between trephining (Elliot) and iridencleisis (Holth). *Klin. M. f. Augenh.*, 1942, May-June, v. 108, p. 303. (See Section 2, Therapeutics and operations.)

Duverger, C., and Bregeat, P. Cataract and chronic glaucoma. *Arch. d'Ophth.*, 1945, v. 5, no. 1, p. 3.

Cataract and chronic glaucoma may occur independently in the same eye, and there is a real danger that the symptoms of the glaucoma may be masked by the cataract which prevents recognition of optic-nerve excavation. Signs which should suggest glaucoma include abnormal dilatation of the pupil, intraocular pressure above 25 mm. Hg, and contraction of the light field, particularly on the nasal side. Distinction must be made between chronic glaucoma and temporary hypertony due to an intumescent lens. The authors recommend an inferior limbal section for cataract extraction in order to conserve the area of the upper limbus for a possible fistulizing procedure. Extracapsular extraction is recommended both for its safety and for the value of the intact posterior lens capsule in preventing the complication of vitreous prolapse into the fistula. The cataract extraction precedes the glaucoma operation, which is a slightly modified Lagrange procedure if the cataract is mature and if the visual field

is good and the hypertony can be controlled by miotics. The glaucoma operation is done first if the visual field is markedly contracted or the hypertony does not respond to miotics.

Phillips Thygeson.

Gradle, H. S. Fundamental ideas in surgical treatment of glaucoma. *Arch. Chilenos de Oft.*, 1945, v. 1, Jan.-Feb., pp. 5-11.

Practically all the measures taken to lower intraocular hypertension attain their purpose by establishing drainage of the aqueous humor. This may be done by restoring the normal drainage channel, opening new intraocular channels, or establishing new extraocular pathways for carrying off the aqueous. Each operation has definite indications. The results of surgical intervention depend on the oculist's diagnostic skill, and on his knowledge and understanding of pathologic changes and of the modus operandi of the various procedures, as well as their operative technique. In a general way, it may be said that 95 percent of cases of glaucoma can be controlled provided that they are not seen too late and that a judicious surgical plan is followed.

W. H. Crisp.

Lehrfeld, L. Revaluation of Herbert's flap operation for glaucoma. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 191-194.

Herbert's original trapdoor or flap operation, devised initially for absolute glaucoma, had, as its basic principle, the drainage of fluid from the interior of the eyeball through an opening in the sclera, in the anterior segment, to the subconjunctival space. Using a narrow Graefe knife, he made an incision in the sclera 2 mm. from the corneal margin in the lower outer

quadrant of the globe. From the two ends of this small incision, two shorter forward cuts were made to the limbus by turning the edge of the same narrow blade forward and sawing carefully to avoid puncturing the iris, in the emptied anterior chamber. He thus created a small rectangular flap or tongue of corneoscleral tissue, which was cut subconjunctivally with its base at the limbus.

Lehrfeld still advises enucleation of all painful blind eyes associated with increased intraocular pressure, but when the patient refuses enucleation, this operation may be tried. He has operated upon the eyes of seven patients of this nature with quite satisfactory results.

If the origin of acute glaucoma is in the vitreous-chamber segment, it seems logical that the new exit of fluids should be made in the silent portion of the eyeball, rather than at the corneal margin. The same holds true for chronic simple glaucoma which has as its basic pathologic conditions arteriosclerosis and fibrosis of the tissues of the eyeball. If one holds to the theory that the canal of Schlemm is so sclerosed and fibrotic that it no longer serves as exit for these fluids then the new exit for these fluids should not be in the obstructed angle, but in the silent areas of the eyeball.

Herbert originally made his anterior sclerotomy 1.5 mm. from the limbus. Later he increased the distance to 2, 3, and 4 mm. Lehrfeld's contribution to the Herbert operation is a further shifting of the exit in the sclera 4 to 8 mm. from the limbus, producing a trapdoor in the region of the eye corresponding to the location of the ciliary body and immediately beyond.

The operation can be repeated at different locations should increased ocular tension return. R. W. Danielson,

Lijó Payá, J. Anterior hemorrhagic glaucoma. *Rev. Oto-Neuro-Oft.*, 1944, v. 19, Oct., pp. 134-140.

This diagnosis is reserved for the secondary glaucoma that follows partial or total occlusion of the central retinal vein or its tributaries, which is associated with rubeosis iridis; which accompanies diabetes with hemorrhages; and which follows massive vitreous or retinal hemorrhage. The author quotes the opinions of other writers as to what data are necessary for such a diagnosis.

The case of a young adult is presented who suffered a trauma to his left eye some years earlier, following which a cataract developed. Vision was reduced to light perception. After a long period of quiet, he suddenly experienced severe pain in the same eye. Examination revealed corneal edema, hyphema of 4 mm., a dilated pupil, and a tension of 80 mm. (Schjdtz). Under pilocarpine 3 percent, and general care, the tension was brought to normal in one month, with no recurrence of corneal edema, and a recession of the hyphema to 2 mm. Rubeosis iridis was also present. After a second month of treatment the hyphema was completely absorbed. The author concludes that anterior hemorrhagic glaucoma is due to mechanical obstruction of the iris angle, since miosis hastens absorption of the attendant hyphema and restores a normal ocular tension. (3 retinographs, references.)

Stocker, F. W. Response of chronic simple glaucoma to treatment with

cyclodiathermy puncture. Arch. of Ophth., 1945, v. 34, Sept., pp. 181-186.

Two types of diathermic treatment have been recommended for glaucoma. Weve, followed by Amsler, was first to use the surface electrode. The perforating type, called cyclodiathermy puncture, was introduced by A. Vogt.

In the beginning Stocker used cyclodiathermy puncture only in desperate cases of glaucoma which had been unsuccessfully treated by several of the various surgical procedures. However, as the author's own experience grew he became more and more convinced that the technique of cyclodiathermy puncture could be so refined as practically to exclude most of the dreaded unfavorable side and after effects. He therefore treated with cyclodiathermy puncture a group of Negroes suffering from chronic simple glaucoma, who had not been previously subjected to any other operation and who ordinarily respond poorly to filtering operations.

Vogt's original idea was to destroy the ciliary body with its processes directly with the coagulating diathermic current. However, when the punctures were applied near the limbus where they reached the corona ciliaris, there was too much reaction, and even necrosis of the cornea occurred. It was found that when cyclodiathermy puncture was applied farther back, to the pars plana of the ciliary body, an adequate lowering of the tension resulted. It must be assumed that by destroying the blood vessels, which are supplied by the long posterior ciliary arteries and reach the corona ciliaris by passing through the pars plana, the circulation of the corona ciliaris becomes impaired to a point at which degeneration and atrophy results. This obviously should ultimately lead to a decrease in

the production of intraocular fluid.

The author recommends close adherence to the technique as outlined. He says, "Vogt's needle, 0.5 mm. long and 0.18 mm. in diameter, or the shortest type of Kronfeld needle may be satisfactory. More recently I have been using exclusively a needle that has been made according to my own suggestions. It is better insulated and may be recommended. Very little current should be used. Vogt used to recommend 60 milliamperes. However, I found that it was not practical to rely on a milliampere meter and that it was necessary to determine at the beginning of the operation how much current is necessary just to produce coagulation on the surface of the sclera. Usually the Walker machine is set between 15 and 20.

"The question then arises how many punctures should be made and how large an area has to be covered. An area beginning from 2.5 to 3 mm. from the limbus to the ora serrata should be covered. Therefore, on the inner side, the punctures must extend back somewhat farther than the insertion of the internal rectus, on the inferior side just about beyond the insertion of the inferior rectus, and the same distance on the external side. If the punctures are applied to the upper part of the globe they should not extend quite as far as the insertion of the superior rectus. The coagulation needle should be left in the sclera a little longer than one second. I count 1, 2, 3 during the procedure. On the count of 1, I introduce the needle, on 3 I remove it. The needle should be under current throughout the procedure. Usually somewhat more than one third of the inferior circumference is treated. We tried to establish a relation between the number of millimeters of mercury of tension and the

number of punctures. We are tentatively following the formula: number of millimeters of mercury of tension plus 30 equals the number of punctures required. However, never more than 80 punctures should be applied in chronic simple glaucoma."

Cyclodiathermy puncture, in 16 cases of chronic simple glaucoma, has proved to be a harmless procedure, as deleterious complications have not developed in any case. Its influence on the tension and the general course of the disease has been generally beneficial. The lowering of the tension has been of long duration.

Cyclodiathermy puncture has certain definite advantages over other operations used for glaucoma simplex. It seems to work regardless of the type of

glaucoma. No late infection is to be feared. No tendency toward stimulating the development of opacities of the lens can be demonstrated. No rapid deterioration after the operation in advanced cases, as frequently seen in some of the other procedures, occurs. It therefore may be applied safely in all stages of chronic simple glaucoma.

As shown in this study, cyclodiathermy puncture is effective also for the Negro and may well become the method of choice for the treatment of the severe disease in this race. A careful observation of the technique as outlined is essential.

A discussion of this paper appears in *Arch. of Ophth.*, 1945, v. 34, p. 346.

R. W. Danielson.

PAN-AMERICAN NOTES

Edited by DR. M. URIBE TRONCOSO
500 West End Avenue, New York

Communications should reach the editor by the twelfth of the month.

MISCELLANEOUS

Chile: New ophthalmological journal. We have received the first four issues of the "Archivos Chilenos de Oftalmologia," a bi-monthly journal published under the editorship of well-known ophthalmologists in Chile. The director is Dr. S. Barrenechea, who has as honorary editors Prof. C. Charlin, director of the University Eye Clinic, and Profs. Martini, Espildora Luque, and Thierry.

Each number contains, besides original articles, the proceedings of the Chile Ophthalmological Society, abstracts, book reviews, and other material.

We wish a long life and complete success to the new journal.

Mexico: The Association for Prevention of Blindness in Mexico has issued a volume of the proceedings of the annual convention held by the association this year. It is a large and well-printed book with many illustrations. There is an introductory statistical review of the ophthalmologic work done in the hospital of the association during the year 1944. The staff includes 12 ophthalmologists, many internes, and nurses. There is also a large out-patient department. The number of operations performed in the hospital during 1944 was 670, a few more than those of the previous year. Next to cataract operations the largest number of operations was for pterygium. This fact illustrates the frequency of this disease in the semi-tropical altitude of Mexico.

In addition to this report the book includes 17 interesting papers. To be mentioned are one dealing with conjunctival involvement of onchocercosis, one with intraocular cysticercus, and others with traumatism of the skull, contact lenses, and angioscotometry. Three papers were contributed by American ophthalmologists, one by Dr. Conrad Berens and C. E. Kerby, another by Dr. Daniel B. Kirby, and the third by Dr. George Guibor. The volume ends with necrological articles and the pictures of Dr. Rafael Silva and Dr. Sanford R. Gifford, of Chicago, outlining the careers and merits of these distinguished ophthalmologists. The book is a worthy addition to ophthalmologic literature in Mexico.

The last numbers (March and August, 1945) of the "Boletín del Hospital Oftalmológico de N.S. de la Luz," of Mexico, contains interesting articles on onchocercosis, clinical applica-

tions of angioscotometry, a new method of suture for cataract operations, and a short article on ocular leprosy.

The National Society for the Prevention of Blindness participated in the Pan-American Congress of Ophthalmology. Mrs. Eleanor Brown Merrill, the executive director, accepted an invitation to participate in this Congress and attended the meetings in the last week of November, 1945. She presented a paper on the subject: "How medical and lay coöperation may be used in national prevention of blindness programs."

In conjunction with the Congress, a special exhibit had been prepared in Spanish, presenting in five large oil paintings the following aspects of the prevention of blindness: (1) How drops at birth save babies' eyes; (2) Pre-school eye care; (3) Need to help establish sight-saving classes; (4) Eye health and safety in industry; and (5) Periodic check-up of the eyes past mid-life. In addition, a smaller exhibit has been prepared on the use of traveling eye clinics for rural patients. These units have been presented to the Pan-American Congress with the thought that, following the meetings, they will be circulated throughout South and Central American countries at the national medical, social work, and educational meetings.

OBITUARIES

Prof. Carlos Charlin. The distinguished professor of ophthalmology of the University of Chile, Dr. Carlos Charlin, died suddenly on August 31, 1945. The funeral was held in the hall of the medical school, where representatives from the Institution, from San Salvador Hospital, from the Chile Ophthalmological Society, and from other associations read addresses outlining the scientific and professional career of Dr. Charlin. The "Archivos Chilenos de Oftalmologia" published a special number in his honor containing a list of his papers and of the nine books on ophthalmology he issued during his long and fruitful life. Professor Charlin was considered the outstanding ophthalmologist of Chile for many years.

Dr. Joaquin Tejeda, a member of the staff of the Hospital of N.S. de la Luz passed away in Mexico, in June, 1945. He was the ophthalmologist in charge of the eye department in the Hospital and Institute for Leprosy near Mexico City. His premature death was a matter of great regret to his colleagues.

NEWS ITEMS

Edited by DR. DONALD J. LYLE
904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month.

DEATHS

Dr. William S. Ankenbrock, Indianapolis, Indiana, died September 28, 1945, aged 49 years.

Dr. Fletcher L. Crocker, Pontiac, Illinois, died August 31, 1945, aged 79 years.

Dr. Edward A. Dignam, Rockville, Connecticut, died August 26, 1945, aged 48 years.

Dr. Albert D. Frost, Columbus, Ohio, died November, 15, 1945, aged 56 years.

Dr. William J. Harkins, Quincy, Massachusetts, died August 25, 1945, aged 59 years.

Dr. Nelson K. Hopkins, Arlington, South Dakota, died July 25, 1945, aged 63 years.

Dr. James W. Jervy, Greenville, South Carolina, died November 1, 1945, aged 71 years.

Dr. William L. Kenney, Saint Joseph, Missouri, died August 11, 1945, aged 72 years.

Dr. Samuel A. Miller, Longview, Texas, died August 28, 1945, aged 78 years.

Dr. Samuel W. S. Toms, Nyack, New York, died August 22, 1945, aged 83 years.

Dr. George G. Van Mater, Peru, Indiana, died August 28, 1945, aged 82 years.

Dr. James W. Wallace, Aledo, Illinois, died August 26, 1945, aged 64 years.

Dr. Benjamin B. Wechsler, Pittsburgh, Pennsylvania, died August 17, 1945, aged 66 years.

Dr. Joseph B. Workman, Ware Shoals, South Carolina, died September 20, 1945, aged 67 years.

MISCELLANEOUS

The Department of Ophthalmology, Northwestern University Medical School, has received an additional gift of \$4,000 to the Sanford R. Gifford Memorial Fund from Mr. Bernard Spero, president of the House of Vision, Chicago. It is proposed to use this sum to establish a fellowship in research and teaching of refraction and allied subjects to young ophthalmologists.

A change in the examination dates of the American Board of Ophthalmology has been announced. The examination originally scheduled to be held in Los Angeles, January 28th-31st has been changed to San Francisco, June 22d-25th. Other examinations will be: New York, about April 14-19th, and Chicago, October 9th-12th. A new ruling requires that previously accepted candidates mail their lists of surgery to the Board office at least 60 days prior to their examination. All new applicants are now required to send their lists with their application.

Dr. S. Judd Beach, Portland, Maine, is secretary-treasurer of the Board.

Washington University School of Medicine in Saint Louis announces a four-week intensive refresher course in ophthalmology from June 3 through June 29, 1946. The 131 hours of didactic lectures will cover the important phases of ophthalmology. The course is designed primarily for the returning veteran, but should also serve as an excellent review for candidates for the examination by the American Board of Ophthalmology. Tuition fee: \$200.00. An outline of the course as well as more detailed information will be sent on request. All applications or inquiries should be addressed to Dr. Richard G. Scobee, Director of Graduate Training in Ophthalmology, Washington University School of Medicine, 640 South Kingshighway, Saint Louis 10, Missouri.

Emory University will hold an ophthalmological seminary honoring the memory of Dr. Abner Wellborn Calhoun, April 4th to 6th. Guest lecturers will be Drs. William Benedict, John Dunnington, Parker Heath, Walter Lillie, Derrick Vail, and Frank Walsh. All members of the ophthalmological profession are cordially invited as guests of Emory University. Make reservations early at the Atlanta Biltmore.

The Oregon Academy of Ophthalmology and Otolaryngology will hold its sixth annual spring postgraduate course in ophthalmology and otolaryngology in Portland, April 15 to 20, 1946. Among the guest speakers will be Dr. Algernon B. Reese, professor of ophthalmology at Columbia University, and Dr. Gabriel Tucker, professor of bronchoscopy and laryngology at University of Pennsylvania Graduate School, Philadelphia.

The third ophthalmologist's office-assistant's course in fundamental optics was held at the Pember-Nuzum Clinic, Janesville, Wisconsin, from February 2d to 16th. Among the participants in giving the course were Dr. Aubrey H. Pember, Selma Weiskopf, Austin B. Belgard, and Ralph Lowrey.

The Gill Memorial Eye, Ear, and Throat Hospital will hold its nineteenth annual spring graduate course in ophthalmology, otology, rhinology, laryngology, facio-maxillary surgery, and bronchoscopy and esophagoscopy, from April

1st to 6th. The courses in ophthalmology will be conducted by Drs. Charles A. Perera, F. Philip Koch, Edmund B. Spaeth, George P. Guibor, Merrill J. King, William F. Hughes, Jr., Frank Payne, and Isaac S. Tassman.

SOCIETIES

The guest speaker of the October dinner meeting of the Cleveland Ophthalmological Club was Dr. John E. L. Keyes, who spoke on "The present status of penicillin in ophthalmology."

Dr. Martin Cohen, professor of ophthalmology in the Graduate School of Columbia University, was the speaker at the December dinner meeting of the Cleveland Ophthalmological Club. Dr. Cohen spoke on "Fundus changes observed in nephritis, diabetes, and hypertension." His talk was illustrated with many beautiful lantern slides. Because of his valuable contribution to ophthalmology, Dr. Cohen was made an honorary member of the Cleveland Ophthalmological Club.

The following officers were elected by the Section on Ophthalmology, College of Physi-

cians of Philadelphia: Dr. Burton Chance, chairman; and Dr. George F. J. Kelly, clerk. Meetings are held the third Thursday of every month from October to April.

The Research Study Club of Los Angeles conducted its fifteenth annual midwinter post-graduate clinical assembly in ophthalmology and otolaryngology from January 21st to February 1st. Guest speakers included Dr. Meyer Wiener, Dr. Frederick C. Cordes, Dr. Herbert M. Evans, and Irving B. Lueck, B.S.

At the January 22d meeting of the Milwaukee Oto-Ophthalmic Society Dr. Avery D. Prangen presented a paper on "Some clinical aspects of refraction."

PERSONALS

Dr. Joseph I. Pascal has just returned from South America where he attended the Pan-American Congress of Ophthalmology held in Montevideo, Uruguay, the week of November 26 to December 2, 1945. Dr. Pascal was a delegate from the New York Society for Clinical Ophthalmology and at the scientific session of the Congress read a paper on "An accommodative unit in corrected ametropia."

The Importance of
CONTACT LENSES
 IN

CORNEAL INJURIES

Corneal scars and opacities are so frequent in their occurrence and so disabling visually it is highly important that *you* are fully aware of the part contact lenses can play in frequently re-

storing useful vision to such patients.

Veterans with corneal injuries who would otherwise be classified as "near blind" today are given useful vision through the use of contact lenses.

The above eyes show a case of lagophthalmus in which the inability to close the lids resulted in corneal ulceration. Vision without spectacles 20/400—;

with spectacles 20/100+; with contact lenses 20/20+. Wearing time—constant use with fluid changes every 6-8 hours.

DIATHERMIC SURGERY OF THE CILIARY BODY
IN GLAUCOMA*

EXPERIMENTAL AND CLINICAL OBSERVATIONS

MANUEL URIBE TRONCOSO, M.D.

New York

HISTORY

Shahan and Post¹ in 1921 were the first to apply heat to the limbus by means of the thermophore in order to obtain a reduction of the intraocular pressure. They used rabbits' eyes and 40 human eyes affected with glaucoma. Curran² (1925) devised an operation which consisted in cauterizing the sclera with the galvano-cautery near the limbus, over an area 8 to 10 mm. in diameter. His purpose was, first, to interfere with the function of the ciliary body at the place of cauterization and, second, to produce a decompression staphyloma. He succeeded in lowering the intraocular pressure, but the effect was temporary. Fiore³ in 1929 reported at the International Congress of Ophthalmology in Amsterdam the results of an operation with the galvano-cautery in which the sclera and ciliary body were perforated several times. He made linear applications in a meridional direction from the limbus to the ora serrata. His idea was, first, to make a destructive coloboma of the ciliary body and reduce edema; and, second, to cut the ciliary muscle ring and allow a freer flow of the

intraocular fluids. According to the author, the operation was performed with success on 177 eyes, the majority of which were affected with acute glaucoma.

Vogt⁴ in 1937 for the first time applied diathermy to the ciliary body with the object of obtaining a reduction of the intraocular pressure in glaucoma. He called this method "cyclodiathermy." The operation consisted of a great number of transcleral punctures (usually 100 or more) made with a special small needle, 0.5 mm. long and 0.18 mm. thick, provided with a stop and using about 60 milliamperes (fig. 1). The needle was pushed vertically into the sclera at intervals of

Fig. 1. Vogt's operation for cyclodiathermy. The severed tendon of the inferior rectus muscle is in the center of the coagulated area.

* From the Department of Ophthalmology, Columbia University, and the Eye Institute of the Presbyterian Hospital. By a grant from the Harriman Glaucoma Fund.

0.5 to 0.25 mm. and left there for one-half to 1 second. The punctures included an area $2\frac{1}{2}$ mm. distant from the corneal limbus and as far back as the insertion

Fig. 2. Albaugh and Dunphy's method of nonperforating diathermy.

of the tendon of the inferior rectus, in front of the ora serrata. Laterally, they reached the insertions of the internal and external recti. The coagulated area thus included from one third to one half of the circumference of the globe.

Vogt stressed the fact that the punctures were made wholly in the orbiculus or pars plana of the ciliary body and that the ciliary processes were not touched. He stated that no theoretical explanation can be given for the action of his operation, but that the damage to the ciliary body (orbiculus in his case) may bring about a reduction of the secretion of the aqueous.

He used his method only in severe cases when all other methods had failed and in hemorrhagic glaucoma. The punctures produced an oozing of the vitreous body and the intraocular pressure was immediately lowered. He reported a case of necrosis of the sclera.

In 1939 Wagner and Richner,⁵ following Vogt's methods, reported 47 operations of this kind for various types of

glaucoma. They claimed that 72 percent were successful. Two cases were studied from the standpoint of pathologic findings.

At the meeting of the American Ophthalmological Society in 1943, Albaugh and Dunphy presented a paper on cyclo-diathermy⁶ in which they described two kinds of operation: first, perforating punctures applied according to the technique of Vogt but limited to only one quadrant of the circumference of the globe. They stated that the original Vogt method gave rise to great inflammatory reaction and had subsequent complications. By their second method a nonperforating diathermy, performed with a flat electrode of the Weve type, was applied 4 to 5 mm. behind the limbus in one row over one half of the globe (fig. 2). The electrode has to be applied hard against the sclera, otherwise there is no penetration of the current and the coagulation effect is only superficial. The authors preferred the latter method of diathermy and used it in 32 cases, with success in 25 and failures in 7 patients. They especially advocated nonperforating cyclo-diathermy when other medical and surgical treatments had failed and when an opening of the globe had to be avoided because of the great danger of a sudden reduction of intraocular pressure.

At a meeting of the Chicago Ophthalmological Society in 1941, Dr. Samuel J. Meyer⁷ gave a preliminary report of diathermy of the ciliary body. In the discussion that followed this communication, Dr. L. Bothman said that in the University of Chicago Clinic the operation had been performed not only on blind, painful, glaucomatous eyes for which other treatment had failed but also on one eye with 20/20 vision and on another with 20/100, with no further loss of vision in either. Although in most instances the tension

rose again in a few weeks, the patient was relieved of unendurable pain. Dr. G. H. Mundt stated that of three patients operated on, two had an excellent result as to tension. Ordinarily, operations can be performed under local anesthesia, but with this kind of procedure it is difficult. Although patients are given morphine and nembutal and fully prepared for surgery, they shrink from the diathermy.

Somewhat more recently, Dr. Dupont Guerry, III,⁸ published an account of his experiments on the use of diathermy to block the long ciliary arteries and obstruct circulation of the ciliary body. He claimed to have obtained good results in producing permanent reduction of intraocular pressure in glaucomatous eyes.

ANATOMIC RELATIONS AND DISTANCES OF THE STRUCTURES OF THE ANGLE IN RABBIT AND MAN

The effect of diathermy varies not only according to the intensity of the current and the depth and length of application but also according to the anatomic place that is coagulated or destroyed. This last factor is of great importance, so that special consideration of the anatomic relationships of the structures in the angle of the anterior chamber is necessary before an operation is undertaken.

The relative distances from the orbiculus and processes to the iris root and angle of the anterior chamber in normal animal and human eyes were measured, freshly enucleated eyes being used which had been kept in formalin for one day. If a puncture is made with a Graefe knife into the sclera of a rabbit's eye, 2 mm. from the limbus on the nasal side, where the processes are longer, the tip of the knife will appear in the ora serrata exactly behind the ciliary body, not having touched the processes at all. When the puncture starts 1 mm. from the limbus, the knife divides

the ciliary processes in half. When puncture is made exactly at the limbus and perpendicular to the scleral wall, the perforation cuts the head of the processes.

In the human eye a cataract knife puncturing the sclera 5 mm. from the limbus runs through the orbiculus but does not touch the processes. When the puncture starts 3 mm. from the limbus and perpendicular to the sclera, the blade perforates the ciliary body exactly behind the processes; when started 2 mm. from the limbus the knife reaches the anterior part of the processes at their base, just behind the iris; when introduced 1 or $1\frac{1}{2}$ mm. behind the limbus, the perforation reaches the angle of the anterior chamber in front of the iris.

Using microscopic slides of normal human eyes one finds the distances of the structures at the upper part of the globe to be as follows: From the limbal edge of the conjunctiva to the bottom of the recess of the anterior chamber, 1 mm.; from the recess of the chamber to the posterior end of the processes, $1\frac{1}{2}$ to 2 mm.; from the recess of the chamber to the ora serrata, from 4 to 5 mm. Sometimes this 5-mm. distance encroaches on the choroid. In view of these relationships it is evident that at 5 mm. and even at 3 mm. from the limbus, the distance at which cyclodiathermy is usually performed in man, only the orbicular region is seared. The processes are not touched, although there is, of course, some indirect effect on the organs, depending upon the intensity of the current and the extent of the coagulated area. It is necessary to make the diathermic puncture from $1\frac{1}{2}$ to 2 mm. behind the limbus in order to reach the head and body of the ciliary processes. It should be remembered that in man the processes are comparatively short and the orbiculus covers a large area. Lagrange, who has made the same

measurements in human eyes, reported the following values: In the upper part of the globe from the edge of the limbus to the sinus of the chamber—1.75 mm.; at the lower part of the globe for the same distance—1.45 mm.; at the nasal side—1 mm.; at the temporal side—1 mm.

PHYSIO-PATHOLOGIC EFFECTS OF DESTRUCTION OF THE CILIARY BODY

It is acknowledged that from a physiologic standpoint the orbiculus has probably no secretory function as regards the production of aqueous. The highly vascularized processes, on the contrary, are the source of this secretion and must be destroyed to a greater or less extent if a diminution of the fluid output and a lowering of the intraocular pressure are contemplated.

Wagenmann⁹ (1890), experimenting on rabbits, found that section of the long posterior ciliary arteries produced a reduction in intraocular pressure by changing the vascular supply of the eye. Verhoeff¹⁰ (1924) removed with a knife a part of the ciliary body to induce a lowering of the intraocular pressure, a method he called "cyclectomy." In support of his idea he mentioned the fact that injuries and inflammations of the ciliary body have a marked tendency to lower the pressure. He also considered that "cyclectomy" might alter the vascular condition in such a way as to reduce the intracapillary blood pressure.

H. Coppez¹¹ (1927 and 1929) reported his experimental work on diathermy in rabbits and concluded that the effect of this procedure is to destroy the ciliary body and thus diminish the amount of aqueous secreted into the anterior chamber. He stated that the results of the operation can be measured more or less by the amount of destruction to the ciliary body. When it is very limited, the tension

returns to normal very soon; but if extensive, the destruction may produce not only a reduction of tension but at length an atrophy of the eyeball. He emphasized the importance of further studies in this direction.

The Weekers¹² made experiments in rabbits and think that the principal action of diathermy is an enormous vasodilation of the uveal vessels at the beginning of the ophthalmotonic reaction. This vasodilation is not limited to the point of application of the diathermy but extends over the whole iris and choroid. When the action of the diathermy is intense, hemorrhages, superficially and within the tissues, and exudations are common. When the limits of safety are passed, complications arise such as hyphema, iritis, cataract, choroiditis, and detachment of the retina. The healing process is slow and iris atrophy may be produced in the sector of the operation. When diathermy is extended to the whole circumference of the limbus, the atrophy of the iris may be so marked that the structure "disappears." Cataract and then atrophy of the globe end the inflammatory process. They believed that the vasodilation of the uvea is the cause of the hypotensive effect, but found this not to be permanent.

Meyer and Sternberg^{12a} believe that the physiologic effect of Vogt's operation is only a "scleral shrinkage" with a consequent decrease in the total volume capacity of the eyeball. This lowers the intraocular pressure, but not always, to within normal limits and gives relief with freedom from pain. When an extensive diathermy is applied, including the complete circumference of the eye over the orbiculus ciliaris, hypertension may occur during the immediate postoperative period. If the tension rises above the systolic blood pressure in the central artery of the retina, the artery becomes occluded. This occurred in one of their cases.

PROCEDURES

EXPERIMENTAL DIATHERMY

The purpose of my experiments was: (1) to repeat the diathermy operations of previous authors and determine their effects on the membranes of the eye and the intraocular pressure; (2) to coagulate directly the ciliary-body base and processes and ascertain what amount of destruction to these organs was necessary to produce a long or even permanent lowering of the intraocular pressure; and (3)

diathermy. A much easier and speedy method of observing the lesions produced was the microanatomic method with the slitlamp microscope which I have described elsewhere.¹³ The eye was sectioned in front of the equator and its anterior half placed in a glass jar filled with a special solution. The specimen was pressed against the glass for observation, the cornea away from the glass. The segment was moved up and down and tilted back to illuminate the lesions and scleral scars. In this way a perfect stereoscopic view of the

Fig. 3 (Troncoso). Tonometric curve in rabbit 7. O.D.

what effects the diathermic coagulation had upon the membranes and functions of the eye.

Ordinary diathermy machines were used, the large Lepel model and, in some animals, the Walker apparatus. At different periods of time after the operations the animal eyes were enucleated and hardened in formalin for two days. Then they were sectioned and submitted to the usual microscopic methods with serial sections made at the site of the operations. I soon found that this procedure was long and did not give a good perspective of the changes produced by the application of

coagulation changes in the processes, orbiculus, and lens was obtained under varying magnifications ($\times 15$ and $\times 30$). After this examination the most important specimens were submitted to serial sectioning and microscopic examination.

I. VOGT'S TRANSCLERAL METHOD

Not being able to obtain Vogt's special needle, I operated with a thin electrode, and the perforations of the sclera were arranged in two parallel rows (instead of Vogt's 100) about 5 mm. distant from the edge of the cornea. In the rabbit the ciliary processes are longer than in man and the

orbiculus ciliaris is reduced to a narrow band so that Vogt's directions could not be followed implicitly. One row of perforations was made in the orbiculus but

Rabbit 7, O.D. Pernostan anesthesia, retrobulbar injection of novocaine. The conjunctiva was divided 2 mm. from the limbus and a flap formed with two parallel meridional incisions. The episcleral tissue was removed and the

Orbiculus ciliaris destroyed; scar tissue formed.

the second went farther back into the choroid.*

*The rabbit was used as the animal easier to handle, on which tonometric measures can be accurately made daily without the use of a general anesthetic. The presence of the membranous extensions of the processes has no bearing on the results of diathermy.

sclera exposed. The indifferent electrode was wrapped in moist gauze and placed under the animal's belly. The perforations were made in two rows including about one quarter of the circumference of the eyeball. The flap was replaced and sutured. The next day the eye was inflamed and the conjunctiva swollen. There was some discharge. The iris and pupil were normal to slitlamp observation. Intraocular pressure was low (fig. 3). The reaction continued to be

intense for four days and gradually diminished. The tension rose to normal after 18 days and then showed wide oscillations. At this time the reaction had subsided and the eye was quiet. The black holes of the perforations showed clearly through the conjunctiva. The animal was kept under observation for four months so that any further effects on the intraocular pressure might be observed.

Microanatomic examination. The enucleated eye was hardened in formalin and sectioned parallel to the equator. Examined under water with the slitlamp microscope ($\times 15$) the effects of the coagulation were clearly shown (fig. 4). The coagulation had affected the orbiculus ciliaris and part of the choroid. The punctures were fused together in a white, brilliant, branched band (A) surrounded above by a dark border of pigment grains (B) which extended beyond to the right to encircle a separated, round, coagulated scar (C). Under the white band, A, there was a semicircle of coagulated orbiculus and choroid which included the seared tips of some processes. The rest of these structures were superficially

Fig. 5. Modified Vogt's method of coagulation of the orbiculus ciliaris in the rabbit.

coagulated but not destroyed. The processes under the hole (C) were also superficially seared. On each side of the changes and all around the limbus, the processes were normal. The equator of the lens appeared scalloped, but there were no

marked opacities of the rest of the lens.

Microscopic examination. There was a proliferation and dispersion of pigment in the choroid and especially in the orbiculus, together with proliferation of the

Fig. 6 (Troncoso). Tonometric curve in rabbit 8.

nonpigmented epithelium of the ciliary body. The blood vessels of the episclera were congested, and there was a leukocytic infiltration of the tissues; some of the leukocytes were laden with pigment. The sclera was somewhat thinned. The reaction extended from just behind the ora serrata to the periphery of the iris. The ciliary processes appeared normal.

In view of the slight action of diathermy on the ciliary processes by Vogt's method, other operations were made perforating the sclera immediately behind the limbus.

II. VOGT'S METHOD MODIFIED

Rabbit 8, O.S. Conjunctival flap as in the previous operation. Diathermic punctures were made in two rows of five punctures each (fig. 5). The scleral holes became black. The flap was replaced and sutured. The input current on the Lepel machine was 4 and the output $1\frac{1}{2}$ degrees. The day after the operation, the reaction of the eye was much more active than after the previous operation, with great chemosis and discharge. The cornea was turbid and there was a slight iritis with exudate over the iris and contracted pupil. The tension came down to 11 mm. and then slowly rose to normal one week later (fig. 6). It fell again and stayed low with oscillations until the 25th day after the operation. The inflammatory reaction continued very

marked; the cornea was hazy and the pupil became oval under atropine. Cicatrization started slowly, and the inflammation subsided entirely about one month after the operation.

Microanatomic examination. The effects of the coagulation were very considerable. There was a brilliant white area of coagulation at the limbus, but the principal effect was apparent in the processes, which were completely destroyed, leaving only small white stumps near the ora serrata. The lesions were similar but not so intense as in figure 12. A peculiar fact was the preservation of the zonular fibers, which could be seen all over the coagulated area as fine, white, parallel threads extending from the ora serrata to the lens. The latter was swollen and seared at the spot in front of the lesions. The choroid showed a great dispersion of pigment.

Microscopic examination. The reaction extended from the periphery of the iris to the ora serrata. The iris was adherent to the posterior surface of the cornea, at this place blocking the angle. There was a marked proliferation of the pigmented and nonpigmented layer of the ciliary body just anterior to the ora serrata. The sclera over the treated area was reduced to about one half or three fourths of its normal thickness. There was an increase in the number of superficial blood vessels. Leukocytic infiltration and some hemorrhages were observed in the tissue. The ciliary processes were swollen and the apices destroyed.

III. NONPERFORATING DIATHERMY

For comparison with the effect of Vogt's operation the nonperforating diathermy of Albaugh and Dunphy was used in several eyes.

Rabbit 13, O.D. A conjunctival flap was cut 7 mm. from the limbus, dissected, and rolled forward with the purpose of having a good protection for the seared spots. Diathermic coagulation was made with a spherical electrode, 1 mm.

in diameter, in one row and about 5 mm. from the limbus (see figure 2). The electrode was pressed hard against the sclera until the membrane became blue-black but without perforating it. Six large spots were made. The input of the current was 3 divisions; the output $3\frac{3}{4}$. The next day the eye showed considerable reaction. The conjunctival flap was swollen, although the cornea was clear and the lens normal. The tension went down to 4 mm. and stayed low for 49 days (fig. 7). It then rose to normal but had another long downward oscillation. Ten days after the operation the

Fig. 7 (Troncoso). Tonometric curve in rabbit 13.

inflammatory reaction was still marked; the pupil was dilated, and the iris had numerous new vessels, observable under the slitlamp microscope. Below the lens capsule there were vertical, opaque streaks. Seventeen days later the eye became quiet; the cornea was clear but the limbus showed great vascularization. The animal was killed $2\frac{1}{2}$ months after the operation.

Microanatomic examination. By transillumination the coagulated spots in the sclera appeared as thin, bluish, semi-transparent circles. This rabbit was an albino, so the coagulation changes were not clearly recognized by differences in pigmentation and color. On the other hand, the greatly increased vascularization was readily observed in the normal processes whereas the coagulated ones were entirely deprived of vessels. Below the six seared scleral patches only two or three processes appeared white, semi-transparent; and bloodless. The coagulation effects were mostly confined to the orbiculus and choroid. The choroidal

veins were greatly hyperemic and formed a beautiful, circular, branching design running parallel to the ora serrata. The lens was opaque at the equator, its contour becoming wavy.

IV. NONPERFORATING DIATHERMY NEAR THE LIMBUS

Rabbit 19. To study the effects of this operation directly over the ciliary processes, the coagulation spots were placed immediately behind the limbus. Six large searing circles were made with the ball electrode with a current input of 3 and an output of $3\frac{1}{2}$. The searing effect depends not only on the intensity of the current, but upon the length of application and amount of pressure over the sclera. The reaction of the eye was very severe the next day, much greater than in previous animals. There was considerable chemosis, discharge, haziness of the cornea, and blood and exudates filled the anterior chamber. The pupil was dilated and the conjunctiva coagulated near the limbus. The inflammation continued to be intense for 15 days and then slowly subsided. The exudate in the anterior chamber became absorbed; the cornea cleared although it was covered above with new vessels. The iris became adherent to the lens upward, but was active. The lens was opaque at the site of the operation. Three weeks after the operation the eye became quiet. Hypotony was marked for 15 days and then the tension returned to normal after some oscillation. In another animal (rabbit 23) the inflammation was much more severe. At the end of two weeks the vascularized cornea began to dilate downwards and finally the ectasia invaded the whole cornea. The eye later became entirely soft and atrophic.

Microanatomic examination. The large coagulated spots on the sclera appeared as brown areas extending beyond the ora serrata. At other places the choroid and retina were fused together and coagulated. Exudates in the shape of membranes or threads extended in places from the ciliary body to the lens. The processes were entirely destroyed for about one third of the circumference of the eyeball. Their original places were filled with brown masses of tissue on which white striae ran parallel. At some spots the coagulated processes had kept their shape.

The corneal opacity was due not only to a direct searing, but also to the obliteration of the perilimbal vessels which considerably disturbed the nutrition of the corneal membrane. The lens was swollen and opaque upward. The eye later became entirely atrophic and soft.

COMMENTS. Perforating diathermy by the method of Vogt from $2\frac{1}{2}$ to 5 mm. from the limbus produced large coagulated areas in the orbiculus ciliaris and choroid but had but a slight, only indirect effect on the processes. The fact that even in the rabbit, which has such long processes and narrow orbiculus, the former were not directly affected indicates that in man, whose orbiculus is so wide and whose processes are small, the Vogt diathermy would be effective especially in the orbiculus. This method produces a severe inflammatory reaction which ends in a cicatricial atrophy of the membranes. The lowering of the tension is only transitory.

When the diathermic punctures were made in the rabbit $1\frac{1}{2}$ mm. from the limbus, the processes were completely destroyed at the site of coagulation. The inflammatory reaction was, however, much more severe. There was an involvement of the iris and lens. The lowering of the ocular tension was only temporary. It is surprising that even after this severe traumatism the eye recovered and did not show externally the great destruction of the inner structures. Probably through a compensatory mechanism, the overaction of the remaining processes raised the tension again to normal.

The nonperforating diathermy of Albaugh and Dunphy, placed 5 mm. behind the limbus, produced not only a coagulation of the orbiculus but also had an effect on the processes, which appeared avascular and seared. Probably on this account, lowering of the ocular tension

was more marked than after the use of the ordinary Vogt method. The reaction had a shorter duration.

Inflammation of the iris and changes in the lens make both of the original methods, perforating and nonperforating, applicable only to old glaucomatous eyes, as a last resort for alleviating pain and lowering the tension. The nonperforating diathermy appears to be the more effective and the less dangerous.

NEW METHODS OF SURGICAL DIATHERMY OF THE CILIARY BODY

In the operations previously described the effect of the diathermy was always spread over a large portion of the orbiculus, ciliary body, and choroid. In the operations that follow, my idea was to limit the diathermic coagulation to a few, three to six, processes and to study the effects that this diminution of the secretory power of the ciliary body may have upon the nutrition of the eye and the balance of the intraocular fluid. Two methods of approach were tried: (1) the posterior route, by incising the sclera 5 mm. from the limbus, as in a cyclodialysis operation, and coagulating the ciliary body through the incision; (2) the anterior route, by sectioning the cornea, performing an iridectomy, and then attacking the ciliary body from in front.

A. DIRECT, LOCALIZED DIATHERMY OF THE CILIARY BODY—SCLERAL ROUTE. Rabbit 6. O.D. After a conjunctival flap was made, a scleral incision 5 mm. from and parallel to the limbus was made, as for a cyclodialysis operation. When the ciliary body was exposed, a spatula was introduced, hugging the inner side of the sclera, and was pushed into the anterior chamber. It was slowly withdrawn without making any lateral movements. In its place a fine diathermy wire was introduced into the anterior chamber and the coagulation current turned on for 10 seconds until the tissue underneath the wire was seared. After the electrode was withdrawn, a small vitreous bead prolapsed but did not rupture. The conjunctival flap was replaced and

sutured. The current input on the Leibel machine was 3 and the output $3\frac{1}{2}$. Two days after the operation there was a slight reaction, with swelling of the flap and discharge. The slitlamp examination showed the cornea to be clear and a small white-red exudate covering the iris at the site of coagulation under the limbus. Seven days later the eye was only slightly inflamed, but an accidental trauma broke the conjunctival suture and allowed a small vitreous hernia to appear. The flap was again sutured into place. On the iris a radial, dark, linear depression showed, due to the coagulation. Two weeks after the operation a slight iritis was present with aqueous flares, deposits of pigment in the lens, and a small posterior synechia. Under the action of atropine the pupil dilated, except upward, and the lens proved to be clear. With the ophthalmoscope a small hemorrhage could be seen in the anterior part of the vitreous. One month after the operation the eye was normal. The hemorrhage had become absorbed and the iris showed a white atrophic spot at the site of the operation. The intraocular pressure was reduced and stayed low for 19 days then rose and remained normal with oscillations for one month.

Microanatomic examination. The scleral scar from the inside (fig. 8) appeared as a round, white, depressed tissue (A) half of which was located beyond the ora serrata and half in the ciliary body, with clear-cut pigmented margins. Pigment was also massed in the choroid (B). About five processes had been entirely destroyed in the area of the corona. They were drawn together in the middle by a mass of cicatricial tissue, made of strong, white strands. On either side of the coagulation the processes were normal. The lens was clear.

Microscopic examination. A localized area of the sclera over the ora serrata was thinned to about one half of its normal thickness. In this area there were leukocytes, red blood cells, and a dispersion of pigment. The adjacent pigmented and nonpigmented epithelium of the ciliary body had proliferated. Near this site were chorioretinal adhesions. The base of the processes was swollen but there was no peripheral synechia.

B. EXTENSIVE DIRECT DIATHERMY OF THE CILIARY BODY. Rabbit 4, O.S. Conjunctival flap as in previous operations. The scleral incision was made 2 mm. from the limbus with the object of reaching the processes more directly. The spatula

of vitreous. The current input for this operation was 3 and the output $3\frac{1}{2}$. The conjunctival flap was sutured. Two days later the eye showed little reaction. The conjunctival flap was swollen and there was some discharge. The cornea was

Fig. 8 (Troncoso). Experimental cyclodiathermy in rabbit 6, O.D. Ciliary process destroyed; scar tissue formed.

was moved laterally, detaching the ciliary body for about one fourth of the circumference, as in ordinary cyclodialysis. The diathermy wire was placed over the ciliary body and moved from side to side, the current being increased gradually until the iris (seen from the front) became seared and changed in color (fig. 9). There was no loss

clear and there was a slight hemorrhage over the iris below the site of operation. Five days later the reaction had subsided; the pupil was contracted. With the slitlamp the iris showed numerous new vessels and a black streak below the wound. The pupil was normal; there was no synechia. The conjunctiva was still swollen.

The intraocular pressure was very low, 9 mm., and remained so for 17 days, after which it rose to normal (17 mm.) with downward oscillations (fig. 10). Twelve days after the operation the coagulated area in the iris took on a white color; the pupil became oval. The scleral edge of the wound, which probably was coagulated, had contracted. Later the scar took a bluish color and was translucent by trans-

Fig. 9 (Troncoso). Direct diathermy of the ciliary body—posterior route. Incision in the sclera as for cyclodialysis. The electric wire was moved from side to side to coagulate the ciliary body extensively.

mitted light. Three weeks after the operation the eye was entirely normal.

Microanatomic examination. This being a white rabbit, the normal processes around the limbus showed great hyperemia, and there was a wreath of congested veins around the ora serrata except at the place of coagulation. The scleral scar, larger than in the previous rabbit, was elliptical, semitransparent, and depressed. Below it, a number of processes (about 6 or 8) had been entirely destroyed, only parallel lines of striae remaining visible over a white, seared background.

Microscopic examination. Over the site of the treated area the sclera was reduced to one half its normal thickness. The

fibrous tissue composing it had changed its staining reaction from green to red, owing to newly formed fibroblastic tissue. Descemet's membrane was ruptured. The overlying processes apparently had become necrotic. They had lost their epithelial elements except along the inner surface where new epithelium had grown over. A network of fibroblastic stroma and newly formed fibroblasts was growing into the necrotic stroma.

C. DIRECT BIPOLAR DIATHERMY OF THE CILIARY BODY. With the purpose of localizing the effect of coagulation between two parallel electrodes and avoiding the passage of current through the indifferent electrode, the bipolar method of coagulation was tried in several animals. Since the two wires or prongs can be moved laterally to increase or decrease the distance between them, the extent of intended coagulation in the tissues can be exactly measured. It should be stressed that the effect of this type of diathermy is considerably stronger than when the ordinary method of coagulation is used.

Rabbit 7, O.S. After the conjunctival flap had been rolled back, a scleral incision was made about 1½ mm. from and parallel to the limbus. The prongs with a 3-mm. separation were pushed directly forward upon the base

Fig. 10 (Troncoso). Tonometric curve of rabbit 4.

of the ciliary body but did not penetrate easily. A spatula was therefore introduced and the ciliary body detached from the sclera for

about 5 mm. The two wires were then introduced as far as the anterior chamber and the current passed for 20 seconds (input 2 and output $1\frac{1}{2}$). Immediately the cornea became hazy and the iris took on a black coloration at the site of coagulation. The flap was then sutured to cover the incision. Two days later, the inflammatory reaction was moderate. The conjunctiva was swollen, the cornea hazy above, and there was a dispersion of pigment in the pupillary area. No hemorrhages were visible. In six days the reaction had subsided. The tension rose considerably after the operation, then became very low, and returned to normal with large oscillations (fig. 11). Surprisingly, the eye recovered quickly after the operation so that on the tenth day it appeared almost normal. The cornea was clear and the pupil active. The animal was killed three months later. In only one of the four rabbits submitted to this method did exudates appear in the anterior chamber and hemorrhage over the iris.

Microanatomic examination. In contrast to the slight inflammatory reaction, the destruction to the ciliary body was enormous (fig. 12). Over the ora serrata were two white scars connected below by a bridge of fibrous tissue, a prolongation of which came down toward the lens. The scar was surrounded by an area of pigment dots in the choroid. The processes were entirely destroyed, shortened in the center, distorted, and coagulated on either side. At the left, strands of fibrous tissue bound the scar to the processes. The lens was swollen and coagulated above. The zonular fibers were probably coagulated but kept their normal arrangement and insertions.

COMMENTS ON THE DIATHERMY METHODS BY THE POSTERIOR ROUTE. The operations previously described establish the fact that direct diathermy of the ciliary-body base and processes is capable of destroying a number of processes without producing intense inflammatory reaction within the eye. The coagulation of a few processes can be obtained with little local effect and without greatly disturbing the nutrition of the eye. In fact it is surprising to observe how slight the general re-

action is and how quickly it subsides. The intraocular pressure in the beginning remains very low, a factor commonly noted in many other operations whereby the sclera is perforated. However, after some time (21 days in rabbit 4), it almost always returns to normal. This latter eventuality is most likely due to a com-

Fig. 11 (Troncoso). Tonometric curve of rabbit 7, O.S.

pensatory mechanism that brings about a hyperemia of the remaining processes and restores the secretion to a normal level. Thus the assumption that a limited destruction of the processes could produce a long, or perhaps a permanent, lowering of the intraocular pressure was not confirmed by the facts. This of course applies only to normal eyes. In congested, glaucomatous eyes, whose processes are usually involved, congested, and edematous, it is probable that the compensatory mechanism referred to will not work so effectively. In simple glaucoma where there are no congestive symptoms, conditions approach those in normal eyes.

Bipolar diathermy was undertaken with the idea of localizing the effect of coagulation to a certain area of the corona ciliaris more effectively than with the ordinary method of indifferent electrode. The experiments proved, however, that the results of the coagulation were enormous, and although the inflammatory reaction was not very marked the bipolar

Fig. 12 (Troncoso). Experimental cyclodiathermy in rabbit 7, O.S. Bipolar method. Ciliary process destroyed; scar tissue formed.

method offered no great advantage over the ordinary form of coagulation.

D. DIATHERMIC SURGERY OF THE CILIARY BODY—ANTERIOR ROUTE. In surgery of the ciliary body, unfortunately, the electric knife cannot be used for excision of a part of the organ as in surgery of the brain. Too many important neighboring structures such as the zonula, lens, and others, would be irreparably dam-

aged. Coagulation by diathermy of a portion that stays in place would not induce so severe a trauma. With this in mind, I undertook the experimental destruction of a part of the corona ciliaris from in front through a wide iridectomy.

Rabbit 19, O.D. A corneal incision was made with a Graefe knife behind the limbus and including about one fourth the circumference of the globe. The iris was grasped with forceps, pulled out, and a broad iridectomy performed. The corneal flap was seized with a straight

forceps and rolled over until the ciliary body was well exposed. In the rabbit, iridectomy detaches the iris root and pectinate fibers from the scleral wall and leaves exposed the iridic portion of the ciliary body which includes the processes. In man, iridectomy exposes the ciliary-body front with the ciliary processes extending downward to the zonular fibers. It is easier to attack the ciliary-body base than the individual processes. A fine diathermic-wire was introduced into the ciliary-body base in a meridional direction, about 1 mm. below the inner surface of the sclera, and pushed back for 2 or 3 mm. inside the black structure (fig. 13). Diathermy is more effective if the tissues are dried before the wire is inserted. The coagulation current was then applied. It was necessary to make 5 or 6 punctures to cover the area in two

Fig. 13 (Troncoso). Direct diathermic surgery of the ciliary body—anterior route. The electric wire penetrated the base of the processes immediately below the limbus to a depth of 2 to 3 mm.

rows. The current input was 2, output 4. A slight amount of vitreous was lost. In this rabbit the structures had a tendency to prolapse through the wound; the conjunctival flap was therefore securely tied over the incision.

The course of the operation was favorable. Two days later the reaction of the eye was scant. The cornea was slightly hazy over the coloboma. Atropine, 1 percent, and sulfathiazole salve were applied. Fifteen days later the eye was quiet. Under slitlamp examination the wound was found not to have closed entirely at the center, a shred of tissue remaining between the lips. The cornea was hazy and showed many new vessels above. The coloboma was normal. Some of the pigment was deposited over the lens, which had a transparent vertical streak under the capsule. The fundus seemed normal. The slight ciliary hernia was touched twice with trichloroacetic acid, and one month later the eye appeared normal, except for a slightly

protruding corneal scar. There was some stippling of the cornea above, and two small posterior synechiae at the base of the coloboma. The lens was clear and the fundus normal to ophthalmoscopic observation. The tension went down after the operation (8 mm.), stayed low for 15 days, and then came back to normal, with up-

Fig. 14 (Troncoso). Tonometric curve of rabbit 19.

ward oscillations (fig. 14). The eye was enucleated two months after operation.

Microanatomic examination. At the site of the coagulation there was a brilliant, fluffy-white spot where the processes were entirely destroyed (fig. 15). Above it lay a seared brown area. A peculiar condition was the curving of the processes, which were drawn toward the scar and blended with it on either side. This adhesion probably involved first the membranous extensions of the processes, peculiar to rabbits' eyes. The ora serrata at the place of operation was irregular and wavy. The lens had a notch at the equator in front of the coagulated area but remained transparent at the center. All other structures around the coagulated area were normal.

Rabbit 20. The same technique was used except that the current was increased to input 3 and output 2 to 3, and a corneal suture was applied. The inflammatory reaction was slight, and the eye returned to normal one week later. From the corneal scar many short, new vessels ran downward. The coloboma was normal and the lens clear. There was no synechia.

The *microanatomic examination* of this eye showed a picture similar to that in the

preceding animal, but the coagulation included the whole length of the folds to the ora serrata. The processes at their bases had the same peculiar curvature and were drawn together to form an arch over the equator of the lens. The latter did not appear involved.

COMMENTS. These experiments show that it is possible to destroy a given area

treatment of glaucomatous eyes. The localized destruction of the ciliary body in these experiments was disappointing because, although it induced an immediate reduction of tension, a permanent hypotony was not obtained. Confirming Coppez's views, I may conclude that when the destruction of the processes is limited to a small number, the intraocular pres-

Fig. 15 (Troncoso). Surgery of the ciliary body of rabbit 19, O.D.

of the ciliary body when pathologic changes are present in the processes, with no great inflammatory reaction or danger to the eye. However the principal purpose of the experimental work reported previously was primarily to determine if a localized destruction of the ciliary processes in a small or large area could by itself produce a permanent hypotony of the eye and to apply these findings to the

sure returns to normal after a shorter or longer period of time. When the destruction is extensive, the great inflammatory reaction and considerable trauma endanger the integrity and functions of the eye and usually fail to produce a permanent hypotony.

E. TRANSLIMBAL DIATHERMY. In view of these results I attempted to combine in

a different operation the advantages of a localized destruction of the processes and the effects of a fistulizing operation through the sclera. The destruction of a few processes does not induce a considerable reaction, and when the scleral wound is healed the cicatrix is soft and probably permeable to the intraocular fluids. The fistula or at least a filtering scar in a thinned sclera can be obtained by making a diathermic puncture in an oblique direction through the limbus until the tip of the wire appears in the anterior chamber. The following experiments show the results of this new approach.

Rabbit 12, O.S. Pernostan anesthesia was used and retrobulbar novocaine injection. An incision 6 mm. long was made in the conjunctiva parallel and about $1\frac{1}{2}$ mm. distal to the limbus. On either side of it a meridional incision was cut out and the flap dissected and rolled back. (It is better to roll it back in order to obtain an unobstructed view of the limbus and anterior chamber.) A diathermy wire of medium thickness was connected to the machine

tion. The current intensity of the Lepel machine was input 2 and output 3 to 4. With the current on, the wire was pressed firmly against the sclera, 2 mm. from the limbus, and pushed gradually in an oblique direction until the tip appeared in the anterior chamber. (Slight lateral movements can be made to increase the size of the puncture.) The angle of perforation should be about 30 to 45 degrees (fig. 16). The time the needle stays in place is very important, for the longer it remains the larger the perforation. The sclera becomes blue-black at the edges of the hole; the iris changes to a darker hue, and usually a line of coagulation

Fig. 17 (Troncoso). Tonometric curve of rabbit 12.

Fig. 16. (Troncoso). Translimbal diathermy to produce a limbal fistula. The electric wire penetrates directly into the scleral limbus in an oblique direction and then into the anterior chamber. It is kept there until the scleral holes become blue-black.

and the panel set for coagulation of tissues. After being wrapped in wet gauze the inert electrode was placed under the belly of the animal. The operator uses a switch pedal or, better, a holder with a finger lever for interrup-

appears over its surface. Although the wire may be rapidly withdrawn, the aqueous frequently flows out through the perforation. The conjunctival flap is then replaced and sutured to the limbus. If the aqueous is not lost, a second oblique perforation can be made, if desired, 5 or 6 mm. away from the first.

In the following days the reaction was slight. The flap was red and a little swollen. Since the rabbit was an albino, the coagulated spot in the iris appeared dark, with a thin brown-red line where its surface was seared. The cornea was clear and the pupil normal. The tension was low (7 mm.), Atropine was instilled. Ten days later the eye was almost normal. Viewed through the slitlamp the cornea showed small punctate opacities in the vicinity of the wound. The iris was covered with new radial vessels, and a slight exudate bound it to the lens at the coagulated spot. One month later the cornea still had punctate exudates; there were some new vessels along its surface. The pupil was free. The conjunctiva encroached slightly upon the cornea at the fistula and was edematous. The intraocular pressure showed a remarkably low curve (fig. 17). From 7 mm. of mercury after the operation it rose to 11 mm. and remained there with small oscillations for over two months, when the rabbit died suddenly from an intercurrent disease.

Fig. 18 (Troncoso). Experimental translimbal diathermy in a white rabbit. Ciliary process destroyed. At the bottom of the gap the perforation of the sclera appears as a thinned round area.

Microanatomic examination. At the site of the operation two processes were entirely destroyed, leaving an empty space in the corona ciliaris (fig. 18). At the bottom of this space the electric puncture appeared as a small round darker area. Three processes on either side of the gap

were coagulated, thinned, shortened, and entirely deprived of vessels. The zonular fibers could be seen running normally over and at the side of the coagulated processes. All around the limbus the remaining processes were intensely hyperemic. The choroidal vessels were also

congested and ran in branched twigs parallel to and all around the ora serrata. The lens was clear throughout. Examined from in front, the specimen showed the puncture as a round, dark depression under the conjunctiva 2 mm. from the limbus. The scar appeared to be closed by new tissue formation. By indirect illumination it looked thin and translucent.

In several rabbits operated on by the same technique, hypotony was always marked, with small oscillations, until the animal was killed.

Translimbal punctures made in man will probably coagulate also the trabeculum and Schlemm's canal if the angle is open at this point. However, it should be remembered that peripheral synechias are quite frequent after other operations; namely, on either side of a trephine opening.

MODIFICATIONS OF THE TRANSLIMBAL OPERATION

A. **SURGICAL KNIFE.** The surgical knife was tried side by side with the coagulation wire in rabbit 15. The knife penetrated more easily and rapidly through the sclera than did the coagulation wire. On the following day the iris showed a white triangle of seared tissue at the surgical penetration, whereas at the site of the coagulation the iris was seared in a larger area. The results of the operation were good and the tension remained low but went back to normal 20 days later. The animal was then killed.

The *microanatomic examination* proved that at the place of perforation with the surgical knife very slight changes had been produced in the processes, whereas at the site of coagulation five processes had been considerably seared. It is necessary to point out that when the intensity of the coagulation is low and the time of application short, the holes heal rapidly

and very little or no effect is produced in the processes (rabbits 15 and 17).

B. **THICKER WIRE.** A wire about the size of an ordinary pin with a sharp point was tried but the penetration power was small. In rabbit 20, the effects were marked. A large number of processes were destroyed (about eight) and the choroid was seared. However, even with this great traumatism the inflammatory reaction was not considerable. In another rabbit, a fibrinous exudate, pink in color, covered the lower half of the pupil. The cornea was slightly turbid and the anterior chamber shallow. Four days later the exudate was absorbed, and the eye became quiet. The lens remained clear. Hypotony was considerable for the whole period with some oscillations.

C. **TRANSLERAL PERFORATION.** A perpendicular perforation was tried on rabbit 21 simultaneously with an ordinary oblique translimbal puncture. The wire was first introduced perpendicular to the sclera, 1½ mm. from the limbus and about 2 mm. in depth. It was kept in place until the sclera turned blue-black. Then a few millimeters away a regular translimbal operation was performed. The idea was to reinforce the effect of the latter and to obtain a greater destruction of the ciliary body. After the operation the reaction was slight; the tension was very low. The cornea was clear and the lens transparent.

Twelve days later the eye was enucleated and the *anatomic examination* showed very great destruction. Around the translateral puncture the processes and choroid were coagulated in a large area and a hemorrhage was present partly over the processes and partly over the equator of the lens. The translimbal puncture at one side had destroyed only four processes and the coagulation was limited.

In another rabbit (rabbit 22, O.S.)

wherein the transcleral perforation was not so large and deep, the coagulation effects were not so marked and no hemorrhages occurred. To be positive that no hemorrhages or excessive destruction had been produced with the ordinary translimbal method, rabbit 22 was killed two days after the operation. The anatomic examination showed that four processes were coagulated, but no hemorrhage nor exudates were apparent.

COMMENTS ON TRANSLIMBAL DIATHERMY. A fistulizing operation combined with the coagulation of a small number of processes had the immediate effect of lowering the intraocular pressure. Experimentally, hypotony has been induced for as long as two months. It has proved to be a safe procedure which does not produce a great inflammatory reaction and can be repeated several times in different sections of the limbus. Usually, however, the scleral puncture closes, leaving a thin, depressed cicatrix. Ordinarily, no iridectomy was performed, so that the intact iris membrane could protect the lens from the effects of heat. However, there is no objection to an iridectomy followed by the translimbal puncture, if the latter is made quickly to avoid great heat near the lens.

In congested, glaucomatous human eyes the severe hyperemic effect of diathermy on the ciliary body and choroid may probably be added to the advantages of the fistulization. As Weekers and other authors have pointed out, it is likely that the active hyperemia produced by diathermy changes the circulatory conditions inside the eye and relieves the congestion and stasis of the inner membranes.

CLINICAL APPLICATIONS. Four translimbal operations have been made in patients suffering from old, congestive-type glaucomas. They have been successful in lowering the intraocular pressure and bringing it to normal, but, unfortunately,

the results have not been permanent and a second or third operation had to be performed. A good lasting effect was obtained, however, in a case of secondary glaucoma following a cataract operation. In general it can be stated that the use of diathermy for lowering intraocular pressure has not fulfilled the expectations that many authors, including myself, have entertained about the considerable advantages of this therapeutic method.

SUMMARY

By experiments on rabbit eyes it has been attempted to determine the physiologic bases of diathermic methods, their action on the intraocular pressure, and the damage done to the ocular structures. Vogt's method of multiple perforations of the sclera in the region of the orbiculus ciliaris had no physiologic basis, for the orbiculus has no part in the secretion of aqueous. The method produced a severe inflammation which ended in atrophy of the orbiculus, and had but little effect on the processes.

Albaugh and Dunphy's method of a nonperforating diathermy also acted especially on the orbiculus, although it did have an indirect effect on the processes. It also induced a severe inflammation which ended in atrophy.

When multiple perforations were made experimentally behind the limbus to reach the processes, the results were severe and these organs were destroyed. If the area of coagulation was extensive, intense reactions with exudates, hemorrhages, and lens changes appeared. In some cases the eye became atrophic.

The author tried to determine by direct local coagulation of a small number of processes whether their destruction could produce a prolonged hypotony. He used two routes of approach: the posterior through the sclera and the anterior through the cornea. By the former

method, after making a scleral incision as in cyclodialysis, he introduced a spatula into the anterior chamber then the diathermy electrode, coagulating the ciliary body base either with a single puncture or by moving the wire laterally. The eyes tolerated the coagulation well, and there was little inflammatory reaction. The intraocular pressure remained low for three weeks but then rose to normal. When the coagulation was more extensive, the reaction was greater, although the eye recovered completely three weeks later. The tension was very low and remained so for 17 days, after which it returned to normal. Slitlamp examination of the enucleated eyes clearly showed the extent of destruction in the processes.

Diathermic coagulations via the anterior approach were made after a corneal incision and a broad iridectomy had uncovered the ciliary body and processes. The electrode was pushed directly into the ciliary-body base above the processes. Four to five coagulations were made. The inflammatory reaction was not severe; the cornea was slightly opaque near the wound, a posterior synechia developed,

and the lens showed a linear opacity. The tension stayed low for 15 days and then returned to normal.

As these methods did not produce a lasting lowering of the intraocular pressure, the author tried to combine the limited destruction of the processes with a fistulizing operation. He called this method a "translimbal diathermy." After making a conjunctival flap, he introduced the diathermic wire boldly through the sclera, 2 mm. behind the limbus and pushed obliquely through the ciliary body until the tip appeared in the anterior chamber. The wire was left in place for a few seconds until the perforation was about 2 mm. wide. The flap was then sutured. In several rabbits he was able to obtain considerable hypotony. The scleral aperture remained open for two to three months but later closed. In some animals a filtering scar was obtained. However, the author considers the results of diathermy disappointing from the standpoint of a permanent lowering of the intraocular pressure.

A CASE OF ATYPICAL ACHROMATOPSIA*

LOUISE L. SLOAN,† PH.D.

Randolph Field, Texas

INTRODUCTION

Typical achromatopsia is characterized by complete absence of chromatic color perception in association with other symptoms attributable to absence or loss of function of the retinal cones. The associated findings are as follows:

(1) Visual acuity is reduced, usually to about 20/200. Other evidences of foveal impairment found frequently but not invariably are nystagmus and a central scotoma.

(2) There is a shortening of the long-wave-length end of the spectrum and a shift in the region of maximum brightness toward the short-wave end.

(3) Exposure of the eyes to light of fairly high intensity produces rapid blinking or partial closure of the lids. This photophobia, unlike that accompanying

disease of the external eye, is apparently not caused by any marked pain nor discomfort, but is an attempt to maintain partial dark adaptation of the retinal rods.

(4) The adaptation curve, showing the thresholds during dark adaptation following exposure of the eye to light of high intensity, differs from normal. The normal curve has two distinct portions; in the first section the thresholds depend upon cone function, in the second upon rod function. In typical achromatopsia only a rod curve is present throughout the entire period of dark adaptation. The thresholds during the first 8 to 10 minutes are consequently higher than those of the normal eye.

In a small number of the reported cases of achromatopsia one or more of the associated characteristics are absent. In collaboration with Newhall in 1942¹ I reviewed the cases of atypical achromatopsia previously reported and described two additional atypical cases and one

* From the Department of Ophthalmology AAF School of Aviation Medicine.

† On leave of absence from the Wilmer Ophthalmological Institute of the Johns Hopkins University and Hospital, 1942-1945.

typical case. In one of the former there was complete loss of chromatic vision and a normal luminosity curve. In a second case there was incomplete loss of chromatic vision, normal visual acuity, no evidence of photophobia, and only a slight shift in the luminosity curve. In 1943, Lewis and Mandelbaum² reported three cases of achromatopsia in which adaptation curves were entirely normal, with two distinct portions such as are customarily attributed respectively to cone and rod response. The findings were typical in all other respects.

PRESENT INVESTIGATION

The present study reports an additional case of achromatopsia in which most of the typical associated findings were absent

lightest gray sample (N9/) was called white, N8/ and N7/ were called gray, N6/ gray or green, N5/ to N3/ green, N2/ and N1/ red. Eight loose samples, whose colors were red, orange, yellow, green, blue, and purple of high chroma (saturation) were then compared in turn with the neutral-value scale. In all but one case it was possible for the subject to find a gray which matched the color exactly. In this one case he reported that the color was slightly darker than N5/. The neutral grays chosen to match each color and the color name, assigned in each case are given in table 1. It will be noted that the subject was quite consistent in applying the name red to low-value (dark) colors and grays, the name green to colors and grays of medium value, and the name

TABLE 1

Colors of Following Munsell Specifications			are Matched to Grays of these Values	Called by these Color Names
Hue	Value	Chroma		
Red	4	12	3	Red
Red	5	12	4	Green
Yellow red	6	12	6-7	Green
Yellow	8	12	8	Gray
Green	5	8	6	Green
Purple blue	3	12	4	Green
Purple	4	12	5	Green
Red purple	4	12	4	Green

The subject was attached to a ground crew in the Army Air Forces. Complete loss of chromatic color perception was suspected from the findings on routine color-vision tests. He had some difficulty in reading the demonstration plate in the American Optical Company charts (a red 12 on a gray background) and had the unusually low score of 2 on the Color Threshold Test.³

Further tests with Munsell colors gave conclusive evidence of achromatopsia. When the subject was shown the neutral value scale in the Munsell Atlas, the

gray to light colors and grays (of high value). The value matches indicate also that reds appeared darker, greens and blues lighter than they do to the average normal eye. The reds, for example, were matched to grays which are to the normal eye, one step lower in value, the greens, blues, and purples matched to grays one step higher in value.

A further series of color matches was made using the Macbeth Illuminometer. The illuminometer was directed toward an opal glass plate illuminated from the rear to a brightness of 263 ml. Each of

the colored filters was interposed in turn between the illuminometer and the opal glass. By adjusting the brightness of the standard field of the instrument, the subject was able in every case to obtain a perfect match between the white and the chromatic photometric fields; that is, they were reported as identical in color as well as in brightness. Columns 1 and 2 of table 2 give the Corning filters used and the color

each case reported that the two fields were identical. The color names assigned to the photometric field, as before, varied with the brightness and tended to be reported as gray when above 50 ml., and as green when below this value. A comparison of the brightness matches with those of the normal subject again shows that red and orange appeared darker than to the normal eye, green and blue lighter.

TABLE 2

Filter Used	Color of Comparison Field	Brightness as Measured by Normal ml.	Brightness as Measured by Subject ml.	Color of Field Reported by Subject
None	White	263.0	253.0	Gray
Corning 5543	Blue	5.64	13.0	Green
Corning 4084	Green	39.8	51.4	Gray
Corning 3482	Orange	160.0	103.0	Gray
Corning 2412	Red	36.9	8.03	Gray "too light to be green"
Corning 2404	Red	17.9	3.21	Probably green

of the comparison field in each case. Column 3 gives the brightnesses of the comparison field as determined by an observer with normal color vision; column 4, the brightnesses as determined by the subject. After the standard and comparison

From these data the extent of the shift in the spectral-luminosity curve can be estimated only. The decrease in relative luminosity of reds and increase in that of blues and greens is not so great as

Fig. 1 (Sloan). Adaptation curve measured on the Hecht Adaptometer with a 3-degree violet test field.

fields were matched by suitable adjustment of the brightness of the latter the subject in

Fig. 2 (Sloan). Adaptation curve measured on the Perimetric Light Sense Tester.

would be expected if the luminosity curve of the spectrum coincided with the normal scotopic curve. It is of interest in this connection that the subject's affection would be classified under protanopia on

the basis of tests with the Rabkin Polychromatic charts, presumably because in these charts the difference in brightness between figure and background was the same for him as for one who is protano-

distinct cone and rod portions, and rod thresholds lower than the average normal values. Figure 3 gives the thresholds of the fully dark-adapted eye from center to periphery in the horizontal meridian.

Fig. 3 (Sloan). Thresholds of fully dark-adapted eye from center to periphery in the horizontal meridian.

pic, and suggests that the shift in the spectral-luminosity curve corresponds to that found in protanopia.

All other characteristics commonly associated with achromatopsia were absent in this subject. The corrected visual acuity was 20/15 in each eye. There was no evidence of photophobia. The curve of dark adaptation after preexposure to high brightness had the usual cone and rod portions.

Figure 1 shows the adaptation curve measured on the Hecht Adaptometer with a 3-degree violet test field. Figure 2 shows the adaptation curve measured on the Perimetric Light Sense Tester⁴ with a 1-degree white test field. Both curves have

These were also measured on the Perimetric Light Sense Tester with a 1-degree white test field. The thresholds are unusually low except in the far periphery, where they are close to the average normal values.

As in normal subjects, the foveal threshold was higher than that of the surrounding regions. Additional deter-

TABLE 3
FOVEAL THRESHOLDS LOG μ L 1-DEGREE TEST FIELD

	Subject	Normal	Normal
1° white	6.24	6.05	5.58
1° red	7.39	5.55	5.29
1° blue	5.04	6.16	5.53

minations of the foveal threshold measured on the Hecht Adaptometer are given in table 3 for the subject under consideration and for two normal subjects. The fixation control was a dim point of light at the center of the 1-degree test field. This device maintains a more accurate control of fixation than does the perimetric fixation target of the Perimetric Light Sense Tester, but the presence of the fixation light may increase the threshold slightly. The threshold for white light was not significantly different from the thresholds of the two normal subjects. The threshold for red was, however, higher and that for blue lower than the corresponding thresholds of the normal subjects. These results are consistent with the previous findings, which indicated a shift in the spectral-luminosity curve toward the short-wave-length end.

The normal visual acuity and the normal foveal threshold for white light indicate that the visual cells of the fovea in certain respects function as cones rather than as rods. They differ from normal cones in having a spectral-luminosity curve intermediate between the cone and rod curves, and resemble rods in their complete lack of color discrimination.

SUMMARY

Studies are reported of a subject with complete loss of color perception and a shift in the spectral-luminosity curve. Other evidences of abnormal cone function were not found. These results and those of previous investigations indicate that no one of the characteristics commonly associated with typical achromatopsia is invariably present.

OCULAR LEPROSY IN PANAMA

A STUDY OF 150 CASES

R. D. HARLEY, LT. COL (MC), A.U.S.

Ancon, Canal Zone, R. de P.

The subject of leprosy has attracted medical writers since the earliest times. Accounts from the Egyptian papyrus tell of a disease resembling leprosy that was evident as early as the reign of Hesepti of the First Dynasty about 4600 B.C.;¹ the Papyrus Ebers shows that it existed in Egypt in 1500 B.C. Numerous references have been made to it in Biblical times regarding diagnosis and prevention, where it was referred to as "Zaarath." "Zaarath" has no doubt been misinterpreted by the translators' of the Bible. Outstanding symptoms such as anesthesia, contractures, nodular formations are not mentioned. The "rising" by which is probably meant eruption of any skin lesion, depigmentation, scaling, and itching are more suggestive of vitiligo, favus, psoriasis, scabies, or the acute exanthemata, the "risings" of which later would disappear after the specified period of isolation. Leprosy as we know it today probably did not exist among the ancient Hebrews. That the disease continues to stir curiosity and thought is a testimony to the bizarreness of the disease. Anyone who has worked with these patients is struck by the pathologic museum that resides in each one of them and the utter relentlessness of the disease process.

Reports in the literature on ocular leprosy have come from nearly all parts of the world where leprosy is found, yet there has been little reported in the past few decades. Leprosy was probably introduced to Panama early in the sixteenth century by the Spanish Conquistadores and later in the slave traffic. It is said that the disease first appeared in the United States about 1750 in the vicinity

of what is now Louisiana. The improvement in our precision instruments for study and the apparent variation in leprosy of the eye in other parts of the world has prompted this study of 150 cases in Panama.

The patients reside, or have resided, in the Palo Seco Leper Colony and present all the observed cases of leprosy in Panama and the Canal Zone at the present time. The census of the colony maintains itself at about 120, since the number of new cases and the number of deaths nearly balance. There are about 10 post-mortem examinations each year on patients from the colony. The superintendent of the leper colony believes that the total number of leprosy cases in Panama probably runs three or four times this number. The chance that these undiagnosed cases in the "Interior" will come under the recognizing eye of a physician is small, since their medical facilities are limited.

As Ophthalmologist to the Palo Seco Leper Colony for the past 3½ years, I have been able to observe the ocular lesions in all stages. Accurate reports have been kept of the visual acuity, and refractions have been done as indicated. Examinations of the face, lids, conjunctivas, lacrimal apparatus, and extraocular motility were made. Loupe and biomicroscopic studies of the irides and corneas, and inspections of the fundi were routinely performed. Smears from the conjunctivas and corneas were examined in 100 cases. Data were collected as to place of birth, race, age, duration, and classification of leprosy in each instance. Accurate reports on the eye are traceable

Fig. 1 (Harley). Mixed leprosy (moderately advanced).

Fig. 2 (Harley). Mixed leprosy (far advanced).

back to 1937, and these data have been included.

Different forms of treatment were tried in conjunction with systemic therapy. Over 25 operations were performed, including 5 enucleations. Histopathologic study has been made of 7 sectioned eyes. Photographs, lantern slides, and movies were made of the more interesting cases.

Fig. 3 (Harley). Nodular leprosy.

GENERAL CHARACTERISTICS, DISTRIBUTION, AND AGE

The bacillus of leprosy, discovered by Hansen in 1874, which is found in nearly all the major lesions, is presumptive evidence of its role as the etiologic agent. *B. leprae* can usually be demonstrated in all the eyes at postmortem examination, especially in the anterior segment. The bacillus is an acid-fast slightly curved or straight rod, is said to be resistant to drying, extremes in temperature, and other unfavorable conditions.

The bodies of lepers which have been dug up after three and four years yield *B. leprae* in profusion.² Arning, in Honolulu, found bacilli in great numbers in the putrid fluids of a cadaver that had been exhumed, three months after burial.

The leprosy bacillus, pathologically, induces a typical granulomatous lesion which manifests itself either as a nodular mass or a diffuse infiltrative process. The disease ordinarily assumes three forms: nodular, anesthetic, or mixed.

Nodular. This form affects all the cutaneous structures, especially the face. The leproma is made up of lymphocytes, fibroblasts, and large monocytes, with an occasional polymorphonuclear cell. The large monocytes phagocytize the leprosy bacilli, become swollen, and then take on the characteristics of "foam cells," due to the frothy appearance of the cytoplasm. These foam cells may aggregate into large multinucleated giant cells (lepra cells). However, there is no focal arrangement, and caseation does not occur, but fibrosis with shrinkage does occur.

Anesthetic. In this form there are usually no foam cells but there is an infiltration of the perineurium and endoneurium by lymphocytes, fibroblasts, and monocytes. Eventually fibrosis occurs, which destroys the nerve tissue by pressure.

Mixed. This form is a combination of the two, but manifests itself clinically in varying degrees of the nodular and anesthetic forms.

Two other types—namely, the macular and tuberculoid forms—exist, but their recognition is less clear cut and does not concern the present subject.

According to Manson-Bahr, 1935,³ nodular leprosy is more common in cold damp climates, whereas nerve leprosy occurs more frequently in warm dry climates.

In our cases none of the purely nodular

Fig. 4 (Harley). Neural leprosy.

Fig. 5 (Harley). Tuberculoidlike lesions in a case of mixed leprosy.

type was found. Twenty-six percent were classified as anesthetic, and 74 percent were mixed. The patients were classified as to place of birth, since there is strong evidence that the disease is contracted during childhood. It was interesting to note that the vast majority of patients from Panama in the past 20 years have come from two relatively localized areas in the interior of Panama; namely, Los Santos and Bocas del Toro.

POSITIVE SEROLOGY

In only three patients was syphilis definitely proved by a history of chancre, a positive darkfield examination, a positive spinal fluid, or other incontrovertible evidence. However, sera from a relatively large number of patients showed a 1- or 3-plus Kahn reaction and often a less positive Wassermann. The incidence of proved syphilis at Palo Seco is lower than that usually given for Negro and mestizo individuals in Panama from the same stratum as that from which the lepers came. Positive blood tests of Negroes and mestizos from 1924 to 1941 varied between 15 percent to 30 percent⁴ according to the year. However, it is probable that a considerable number of these persons had a positive reaction from other causes.

Each leper patient had at least five or six blood tests for syphilis, but the tests varied considerably in their positiveness and often became negative for both the Wassermann and Kahn. Nearly all the nodular cases (that is mixed) showed a positive blood test for syphilis at one time, usually picked up by the Kahn test. The neural cases, it was found, were less likely to give a positive test unless there was an acute tuberculoid reaction. Syphilis, apparently, does not alter the course of leprosy except, perhaps, to involve some structures which leprosy ordinarily does not attack.

IMMUNITY IN LEPROSY

The question of allergy has been investigated, but, as in the use of tuberculin, there are certain breaches in its interpretation which are difficult to comprehend fully and apply clinically.

Rotberg⁵ studied the reactions to Lepromin (antigen from nodules) in 1,529 individuals. He concluded that leprosy is a highly contagious but also a highly immunizing disease. The bacillary leper is the propagator of the infection, but prolonged contact with this type of case does not necessarily mean that the disease can be contracted. In countries where it is endemic a large part of the population has been contaminated and immunized. A predisposition to leprosy exists which is represented by a failure of reaction of the immuno-allergy to the bacillary invasion. The greater ratio of cases of "declared" leprosy in familial foci is due, probably, to inherited predisposition, to superinfections, and to the endemic zone of environment. There seems to be little doubt, at present, that susceptibility to the disease varies greatly in different individuals. Healthy adult individuals with good nutrition appear relatively immune to leprosy.

DISTRIBUTION OF PATIENTS ACCORDING TO PLACE OF BIRTH

<i>Country</i>	<i>Percentage</i>
Panama	70
Jamaica	10
Colombia	5
Costa Rica	5
Barbados	3
China	1
Guadaloupe	1
Haiti	1
Martinique	1
Nicaragua	1
St. Lucia	1
St. Vincent	1

The youngest patient examined at Palo Seco was 12 years of age and the oldest 85. In general, the patients who had had the disease for a considerable period of time showed the most severe ocular complications. In fact, it may be said that these patients uniformly showed varying degrees of ocular leprosy proportional to the length of their illness. Those who apparently contracted the disease later in life, or in whom it became manifest later, showed distinctly milder and less rapid ocular changes. Although there was a majority of males at the colony, no actual sex difference could be recognized. Approximately 10 percent of the patients became "smear negative" and were paroled, but 50 percent of these returned to die with the disease. Some of the patients who became eligible for parole declined to leave, preferring the "easy going" routine life of the colony to the struggle of the outside world.

OCULAR INVOLVEMENT

Reports from the literature show that the eye is frequently involved in the systemic disease process. It seems to be generally agreed that the eye presents a very real and serious complication in leprosy. However, the percentage of cases showing ocular involvement, as recorded, varies from 20 to 100 percent of all patients when the different forms of the disease are taken into account (Neve,⁶ Minder,⁷ de Barros,⁸ Wood,⁹ Borthen and Lie,¹⁰ and others). It is probably true that the disease assumes different rates of incidence and manifestations in outlying parts of the world, and this may account for the variations in the reports that have been published. It is known, for instance, that leprosy appeared in Europe about the sixth and seventh centuries and apparently spread with the Crusaders. By the twelfth and thirteenth centuries it spread

with nearly epidemic proportions, so that it was known throughout Europe. At the end of the sixteenth century, through the efforts of segregation, it was considered to have nearly died out. Practically any disease introduced to a virgin people may be expected to be more serious and entail extensive complications; so it may be with the ocular complications of leprosy in different countries.

It was noted that the lowest percentages of ocular involvement emanated from the older civilizations although the significance of this may be questioned. Some authors state that all leprosy patients will eventually have ocular complications. Grossman¹¹ stated that patients with cutaneous (nodular) leprosy always have ocular complications. Pinkerton¹² in Hawaii and Prendergast¹³ in Louisiana reported involvement of the eyes by leprosy in approximately 91 percent of cases.

At Palo Seco the figures corresponded almost exactly with those of the last two authors. Ninety percent of the leprosy patients were found to have ocular involvement, not including the adnexa. If the adnexa were included it may be assumed that in predominantly nodular leprosy all but those in the first few years of their disease have involvement about the eyes. It seems likely, as has been stated, that some form of ocular leprosy will eventually occur if the patient lives long enough. The 10 percent of eyes free from the disease were found exclusively in recent or paroled patients. It was impressive to note that of all the organs involved in leprosy the ocular lesions appeared to cause more complaints than any other.

Lopez¹⁴ calls attention to the dullness of the leper's eyes. It is indeed an observation of some value. The eyes seem to have a dull, lusterless, expressionless ap-

pearance even before notable ocular pathologic change is apparent. Perhaps this is just an outward expression of the greater or lesser degree of depression which inevitably accompanies this disease process.

It was noted that the most severe ocular involvement occurred in those patients who had extensive nodular development. In our series all these cases were classified as mixed, since there were no cases in the colony which could be diagnosed as purely nodular. Even in the anesthetic cases of long duration the ocular pathologic change seemed to be less severe.

ACQUISITION OF THE DISEASE

Even though the organism and pathologic lesions present in leprosy have been accurately described, there is, as yet, no definite idea of how the disease occurs, except that it is probably contagious. The fact that it seemed to run in families led the early leprologists to believe that the disease was hereditary. Of the numerous offspring of Norwegian lepers who emigrated to America, seven definite cases of leprosy occurred in the first generation and one of doubtful diagnosis in the second generation. It is noteworthy that although acid-fast bacilli have been detected in the placenta and cord, no children have been known to develop leprosy if removed from the parents at birth. At Palo Seco the patients are allowed to marry within the colony. The children who have resulted from these unions are known to be thus far free from the disease. The evidence is that the disease is not hereditary.

Authorities now believe that leprosy is transmitted by contagion, usually in childhood. However, the factors influencing contagion appear to vary within wide limits. A number of years must intervene, apparently, between contact of the susceptible host and the manifest disease.

Pinkerton¹⁵ stated that after the first leprosy lesion had been noted there was an average of two years of freedom before the patient became a menace to the community and was apprehended and quarantined. Many attempts have been made to transfer leprosy to man by inoculation. Most of the trials have been futile, but in one experimental and in several accidental inoculations there were positive reactions. The disease, in these instances, appeared milder and was apparently self-limited. Another case of inoculation was in a Sandwich Islander, who within a month developed a leprotic neuritis followed by death within six years. It was revealed that members of his family were lepers, so this finding nullified the experiment (Manson-Bahr³). Father Damien's (Molokai Island) was one of the few adult cases of contagion through contact on record, but even in his case the evidence was not complete.

Not only is the method of transmission in dispute but there is still much speculation as to the medium of transfer. The portal of entry for the ocular invasion is also in question. It is believed by some that the bacilli enter the eye externally from the conjunctiva or episcleral tissues. Most workers are of the opinion that the ocular infection is secondary to a hematogenous spread. The fact that the bacilli can be found in nearly all the internal organs is an outcome of the bacillemia which occurs in most cases of cutaneous leprosy. The "acute leprosy reaction" accompanied by high fever is probably a bacillemia. In favor of the hematogenous spread to the eye is an article by Fuchs,¹⁶ who found the primary ocular lesions in the anterior part of the ciliary body and major circle of the iris. This region has a rich vascular plexus such as would be a convenient receiving end organ for the bacilli. Fuchs found that bacilli may appear in healthy tissues

but did not necessarily affect the tissues. The behavior of the tissues toward the bacilli was the decisive factor. In five sectioned eyes it was shown that inflammation occurred in the perilimbal episclera and the longitudinal fibers of the ciliary muscle extending back to the ora serrata but no farther. Occasionally, healed chorioretinitis occurred, but this was unaccompanied by bacilli, thus casting doubt on its leprous origin. In all cases the cyclitis appeared to be an older inflammation than the episcleritis, which added to the evidence of an endogenous spread.

Santonastaso¹⁷ in studying eight sectioned eyes was chiefly concerned with the localization and extent of the ocular pathologic process. Assuming that there was an exogenous spread of bacilli into the eye and that the limbus was the site of selection, it might be expected that the oldest and most advanced pathologic change would occur at the limbus. This, however, does not seem to be the case, for frequently the iris and ciliary body were more advanced pathologically, thus suggesting an endogenous origin for this site. There appeared to be two factors, exogenous and endogenous, which seemed to be acting simultaneously in this disease. In some eyes one factor often predominated over the other, so that pathologically the response of the ocular tissues to the bacilli differed in age and extent. On the contrary, because other workers have been unable to find bacilli in the small vessels of the iris or ciliary body they have raised objection to the theory of blood-borne transference. Santonastaso has correlated the presence of argentophile fibers with the presence of leprous involvement in the eye. Argentophile fibers may be found especially in the submucosal layer of the bulbar and palpebral fold of the conjunctiva, uveal tract, ciliary

muscle, iris stroma, pectinate ligament, Schlemm's canal, and about blood vessels. Since the leprous involvement closely followed the distribution of argentophile fibers they have been assumed to have a real significance. However, the cornea is peculiarly lacking in these fibers. It is believed that the cornea is attacked secondarily and suffers chiefly through a toxic or trophic agent. This observation, though attractive, appears to be a coincidence rather than a reality. The disease primarily strikes the anterior segment of the eye, and it is in this region that bacilli are most often encountered. The argentophile theory makes it difficult to account for the scarcity of the disease in the posterior segment, where uveal tissues (argentophile fibers) are prominent.

Dimitry¹⁸ and others have called attention to the high percentage of ocular cases that showed marked nasal pathologic change. The cases at Palo Seco exhibited the same association. It is unusual to see any pronounced ocular complication not accompanied by varying degrees of nasal mucous-membrane ulceration and perforation. The possibility of an ascending infection by way of the nasolacrimal duct is to be considered, but purulent dacryocystitis is not seen as commonly as might be suspected, even though the cartilaginous portion of the nose is completely depressed.

VISION AND INVOLVEMENT IN AUTHOR'S SERIES

VISION AND VISUAL LOSS

In the series of 150 patients, the number of eyes examined constituted a total of 298. Twenty, or approximately 13 percent of the patients, were found to be totally blind in one or both eyes. Sixty-two, or 41 percent of the patients, had vision of 20/200 or less in one or both eyes, not correctable, which, in most in-

Fig. 6 (Harley). Corneal leproma in mixed leprosy.

stances, may be assumed to be due to the disease. In 65, or 43 percent, there was normal vision in both eyes. Sixteen, or approximately 10 percent, had normal vision in one eye. The normal vision of these patients had no bearing on the pathologic change, which was later recognized by slitlamp observation. It is impressive that the gross appearance of the eyes in so many of these cases was disproportionate to the findings by biomicroscopy. Thus 82, or 54 percent, of the patients were blind or had vision of 20/200 or less in one or both eyes. This

Fig. 7 (Harley). Close-up view of corneal leproma in mixed leprosy.

may be regarded as the percentage of the colony with severe ocular complications of leprosy. Neve⁶ found 13 blind eyes in 80 patients in India, and Van Driel¹⁰ collected but 7 cases of blindness in 1,300 cases examined in Sumatra. Certainly the factor of blindness must vary with nutrition, environment, stage of the disease, and medical care.

THE ADNEXA OF THE EYE

Leprosy involves the region of the eyebrows and eyelids with considerable frequency. Because this is true such involvement is probably one of the best-known signs recognized by physicians and laymen alike.

Approximately 50 percent of the patients had hypertrophy of the skin of the brows or cutaneous nodules, with varying degrees of loss of hair of the eyebrows or lashes (madarosis). This represented the percentage of patients with far-advanced nodular leprosy. Although loss of the eyebrows and eyelashes is usually given as an early and characteristic feature of the disease, this condition, as a rule, has been found in only the most developed cases. It cannot be regarded as an early sign. The hair changes begin with slight loss in the temporal regions of the eyebrows. Sometimes they become gray, splintered, or softly filamentous. The eyebrows are usually lost before the eyelashes. Frequently a few fine eyelashes persist until the last, especially along the lower lids.

In nodular leprosy, formation of nodules about the outer eyebrows is common. This spot, in addition to the ear lobes, serves as an excellent place to make a puncture for serum smears in the diagnosis of the disease. The margin of the eyelid, usually the upper, may be attacked by nodules. Sometimes these closely resemble chalazia and commonly cause localized pain. Lepromas, the size of large

peas, were found at the margins of three lids. These nodules may ulcerate. A diffuse infiltration of the eyelid margins was also seen which gave the edges a rolled thickened appearance (tylosis). Nodules are also commonly situated about the alae of the nose, on the cheeks, forehead, lips, and ears. The nodules, as they increase in size, seem to accentuate the normal skin folds and wrinkles until there develops what everyone knows as "leonine facies."

In anesthetic leprosy isolated areas of diminished or absent sensitivity occur in the skin about the eyes. They may usually be recognized by differing slightly in color from the rest of the skin. In 15 cases or 10 percent, there was paresis of the orbicularis palpebrarum (lagophthalmos), to the extent that there was incomplete closure of the lids. Fully another 10 percent of patients showed weakness of lid closure when attempt was made manually to elevate the lowered upper lid. In each case the involvement was bilateral but differed in intensity between the right and left side. The cases exhibiting lagophthalmos were in the purely neural and mixed types alike. Sometimes the entire peripheral seventh nerve on one side was involved, with the typical deformity, but it invariably seemed to affect the mobility of the lids to a greater extent. A search was made in each case for a nodule over the affected nerve branch, but none was ever demonstrable. The affection appeared to be a pure neural one and curiously involved the lids out of proportion to the other structures. With the lagophthalmos occurred relaxation and atonicity of the lower lids, commonly resulting in a paralytic ectropion. Ectropion was found in 11 of the 15 cases of lagophthalmos. In the other cases eversion of the lower lid will doubtless develop as time goes on. Exposure keratitis, excessive lacrimation

Fig. 8 (Harley). Section of leprosy skin. Masses of epithelioid cells and lymphocytes have collected beneath the surface epithelium.

with tears spilling down the cheeks, and loss of the natural protective barrier which the lids afford are the usual sequelae of such a complication.

Certain areas of the skin which appear to be free from nodules in skin leprosy have been noted. One of these is located in the upper and lower folds of the lids.

Fig. 9 (Harley). Section of peripheral nerve. Perineural and endoneural cellular infiltrations which are gradually being replaced by connective tissue.

No nodules were ever found in these folds, which are protected so well by the orbital rim. The protection thus afforded to these skin areas appears to play a dominant role and suggests itself strongly as a prophylactic measure. This protective measure has also been advocated by Valle.²⁰ At Palo Seco, where there is a predominance of the Catholic faith, it has been noted that particularly troublesome nodules have developed just below the knee. Apparently trauma as well plays a role in the formation of nodules.

Prendergast¹³ pointed out the relatively common occurrence of xanthelasma of the adnexa among lepers. This condition was found to be associated with a disturbed cholesterol metabolism. No xanthelasmas were seen in our patients, though perhaps the nearly universal dark pigmentation made this condition less recognizable.

A purulent dacryocystitis was seen in four cases but it is suspected that involvement of the tear sac is much more common than this figure would indicate. Stricture or other occlusive phenomena of the nasolacrimal duct which leads to a frankly manifest tear-sac infection is probably always secondary to nasal pathologic change. The complete collapse of the tip of the nose seemed to cause fewer complete duct obstructions than might be imagined.

CONJUNCTIVA

A chronic conjunctivitis occurred in 60, or 40 percent, of the 150 patients, whereas in only 20 percent was the discharge sufficiently annoying to evoke complaints from the patient. The conjunctivitis in all instances closely resembled a chronic catarrhal type with profuse mucopurulent discharge. In the other 20 percent the conjunctivitis consisted chiefly of a chronic injection of the conjunctival vessels, espe-

cially in the exposed portion between the lids and about the limbus. The ease with which far-advanced patients could tolerate the profuse mucopurulent secretions was probably due to the partially diminished sensitivity of the conjunctiva and cornea which occurs in individuals with lagophthalmos in the neural and mixed types of leprosy. However, complete absence of sensation of the conjunctiva was never demonstrated.

Duke-Elder²¹ states that nodules appear with great frequency in the conjunctiva in the nodular and mixed forms. However, Pinkerton and Prendergast express the opinion that the conjunctiva shows little involvement and appears to be one of the fairly immune ocular tissues.

Only two lepromatous plaques were found in the series of cases studied at Palo Seco. These occurred on the palpebral conjunctiva of the upper lid in conjunction with a particularly severe conjunctivitis as flat, infiltrated, irregularly circular areas with an ulcerated center. Leproma of the limbus will be considered with the involvement of the cornea.

Conjunctival smears were made from the inferior cul-de-sac in 100 cases. Eight smears were found to contain acid-fast bacilli. Fuchs mentions that Arizumi found bacilli in the tears of 66 percent of the patients. Riad²² found the lacrimal secretion negative in 108 cases as did Rogers and Muir²³ and Van Driel in their cases. The wide variation in these findings suggests that the bacilli may occur in the conjunctival secretions as an incidental finding from the skin and nasal secretions, internally from the episcleral tissues about the limbus, or from the blood stream. One fact remains clear, however; namely, that the conjunctiva is apparently more immune than the other ocular structures.

Thirty, or 20 percent, of the eyes contained pterygia which for the most part had an atrophic type of head and did not require surgical treatment. They appeared more prominent, owing to the conjunctival injection. Considering the relative frequency with which pterygia occur in the general population throughout Panama, the question of its presence as a complication may be dismissed. One patient showed near the temporal limbus a Bitot's spot which disappeared following the administration of vitamin A for 10 days.

Fig. 10 (Harley). Leprous keratitis and iridocyclitis.

CORNEA

The cornea appeared to be the most vulnerable of the ocular tissues that succumbed to leprosy. Involvement of this structure was recognized in 87 cases and frequently was the only site in which any pathologic change could be seen. Elliot²⁴ and other investigators have classified three principal lesions: (1) pannus or infected granulation tissue which extends in from the limbus, (2) a superficial punctate keratitis and, (3) a deep interstitial keratitis.

The most commonly observed corneal

Fig. 11 (Harley). Small leproma of the cornea. Note the cellular infiltration beneath the corneal epithelium.

lesion was superficial keratitis, which occurred in over 34 percent of all cases. This usually began as a light milky haze punctuated by tiny white dots at the superior or superior-temporal limbus. The lower margin was usually well delineated by a wavy line, and the whole involved area gave the impression of finely pulverized "chalk" or "flour" dust, as has been described by other observers. The lesion showed a generalized haze into which were sprinkled tiny aggregations

Fig. 12 (Harley). Corneal leproma. Higher-power view of figure 11.

Fig. 13 (Harley). Leprous interstitial keratitis. Note irregular thickening and iris atrophy.

of pinpoint white dots. Many small vascular loops often crossed the limbus to enter the lesion beneath Bowman's membrane. In the majority of corneas the lower limit was 2.0 to 3.0 mm. above the pupillary center of the cornea, so that vision was not impaired and the patient was unaware of the lesion hidden by the upper lid. These lesions were also observed to arise from the nasal and inferior limbus. The superficial keratitis of leprosy may be easily overlooked. It is hidden under the upper lid and usually requires good light and magnification such as a slitlamp provides. Trantas²⁵ describes an epithelial and subepithelial keratitis. The former is transient and disappears in a few days, leaving the subepithelial form which is so commonly observed. That both forms are simply phases of the well-known superficial leprous keratitis needs no further substantiation. The latter term should be used to cover both forms. This form of superficial punctate keratitis may be regarded as one of the most diagnostic lesions of ocular leprosy—the other being

the tiny lepromata occurring in the iris, which will be referred to later.

Histologic examination of these corneas showed aggregations of round cells and polymorphonuclears beneath Bowman's membrane, leaving the corneal epithelium fairly well intact. Lepra cells were identified; aggregations of lepra bacilli have been described (Suganumo and Hojo²⁶). The lesions resemble those seen in cutaneous leprosy. The keratitis has been observed to thin out as it approaches the center of the cornea, which, perhaps, accounts for the good vision that often seems out of proportion to the corneal haze.

In 23 cases a frank interstitial keratitis was recognized. This appeared indistinguishable from luetic interstitial keratitis. King²⁷ states that such interstitial involvement does not tend to become less dense with time as does the luetic type. There were five other cases in which a grayish infiltration was present in the periphery, resembling an arcus senilis. However, in these cases vascular loops were present over the limbal border, and they may have represented the beginning of future interstitial keratitides. In 12 additional cases vascularization extending 1.0 to 2.0 mm. into the corneal substance was noted.

A frank pannus was recognized in

Fig. 14 (Harley). Larger leproma of cornea.

seven cases but was in no way different from the pannus seen in other conditions. The granulation was anterior to the cornea but destroyed it as the granulating mass descended. This was evidenced by the vascularization and area of infiltration that preceded it.

The most unusual lesion of the cornea was the giant leproma that occurred in three cases. In each instance it was engrafted on the cornea from a superficial keratitis and looked like a massive epithelioma. Scrapings from these lesions showed them to be teeming with lepra bacilli. Histologically, the corneal epithelium was epidermalized and occasionally ulcerated. Bowman's membrane was generally absent, and calcium deposits were present in its remaining fragments. Inflammatory granulation tissue intervened between the normal epithelium and substantia which was involved. Infiltrating the mass were lymphocytes, plasma cells, polymorphonuclears, and predominantly large foamy wandering cells. It has been suggested that the pathologic corneal changes represent different stages of the same process, and this may be true. Or, perhaps, the different corneal lesions are a result of the varying grades of "tissue resistance" to be found in the host. Six lepromas were situated at the limbus, a relatively frequent site, probably owing to the rich vascular supply at this location. Leprous keratitis is further characterized by its indolent nature without the usual inflammatory reaction.

Gabriélides²⁸ and Pillat²⁹ found bacilli in superficial corneal scrapings and emphasized this point in the diagnosis of ocular leprosy. However, in our cases it was not possible to demonstrate bacilli in superficial scrapings where only the epithelium was removed. Bacilli were, of course, present in the cornea, but it was necessary to scrape to or include Bow-

man's membrane in order to show them easily. This point was borne out by their location histologically.

The "beading" of the corneal nerves seen under high magnification is an interesting sight and easily overlooked. It was found in five cases but may be more common than this.

Corneal anesthesia is stressed almost universally in the textbooks. Yet, on repeated testings, it was possible to demonstrate this satisfactorily in but two far-advanced cases, in which the eyes were phthisical. When a small wisp of cotton was used, a relative loss of sensation was shown in a small number of cases (5). Still, when the cornea was lightly touched with a sharpened toothpick a sensation of pain was easily evoked. In general, it would seem that in the cases observed at Palo Seco complete corneal anesthesia is a rarity. De Barros⁸ of Brazil noted the same persistence of corneal sensation and suggested the need for uniform testing material, such as Von Frey's hair.

UVEAL TRACT

Second only to the cornea, the iris is the structure most frequently involved clinically in ocular leprosy. The most common form of iritis is the chronic recurrent inflammation which insidiously recurs until the most severe sequelae have risen. It comes on typically at one- to six-month intervals, lasting one to three weeks at each attack, depending on the treatment instituted.

Iritis or its sequelae (posterior synechia, ectropion uvae, anterior capsular pigment deposits, or lepromas) were recognized in over 50 percent of the cases. It was usually bilateral and at about the same stage, although the acute recurrent attacks rarely involved both eyes at the same time, except when in conjunction with the "acute lepra reaction." This lepra

Fig. 15 (Harley). Iris angle in leproma section. Note the infiltration and atrophy of the ciliary body. The drainage angle is completely obscured.

Fig. 16 (Harley). Leprous iridocyclitis. The ciliary body is atrophic and the processes are edematous.

reaction is a hyperpyrexia state accompanied by cellulitis-like areas on the skin and supposedly a transient bacillema. Van Poole³⁰ also noted the occurrence of iritis with the acute lepra reaction.

Iris atrophy is a common finding in the older cases. This is represented by a "flattening" of the iris pattern as a whole

Fig. 17 (Harley). Leprous cyclitis. Within the ciliary body there are some rather large round and oblong basophilic vesicular bodies. These appear to be encysted and often included within multinucleated giant cells. Acid-fast stain reveals *B. leprae* in the encysted body.

Fig. 18 (Harley). High-power section of corneal leproma. Lepra cells in corneal leproma.

Fig. 19 (Harley). *B. leprae* in corneal leproma.

and loss of the anterior iris architecture or stroma. In the flat irides a peculiar fine, grayish fibrosis can be seen throughout the interstices of the stroma. Keratitic precipitates and cells are frequently seen under the slitlamp when with ordinary inspection the eye seems quiet.

The most fascinating slitlamp picture of the iris was the tiny lepromas which were seen in over 26 percent of the cases. They occurred always on the background of an old iritis. Typically, they were grayish-yellow, pedunculated, pin-point-sized bodies about the pupillary rim of the iris. However, they occurred deeper in the iris stroma throughout the iris and sometimes in tiny clusters. More rarely they may be seen about the periphery of the iris near the corneoscleral junction.

In two cases larger lepromas were noted. These also stood out from the anterior surface of the iris near the iris angle, and one measured 2.0 mm. in diameter. It developed to this size within one month and then completely regressed within nine months, leaving an atrophic scar in its place on the iris. Incidentally, this patient had a giant leproma of the cornea of his other eye and his brother also had a leproma of the iris which later melted in similar fashion.

It is natural to assume that the ciliary body and at least the anterior portion of the choroid would be involved, although this is perhaps more difficult to demonstrate clinically. It is probably likely, as other writers have suggested, that bacilli come to the ciliary body via the blood stream and diffuse onto the iris or back to the choroid.

Histologically, the sectioned eyes showed infiltration of the ciliary body, iris, and anterior choroid by plasma cells, large mononuclears, and lymphocytes. Leprosy cells and bacilli were also demonstrated. The ciliary processes were some-

times found to be adherent to the posterior iris surface, and often atrophy of the ciliary body was easily demonstrable. Cyclitic membranes were present in far-advanced specimens. The pathology of the choroid was always limited to the anterior portion and closely resembled that found in the ciliary body, but perhaps less marked. Leprous involvement of the ciliary body causes destruction of the zonule and subluxation of the lens.

Iridectomy was performed in a few instances to see if this might lessen the attacks of iritis. The iris was found to be exceedingly friable, and pigment readily diffused throughout the collapsed anterior chamber.

Contrary to what one might suspect, secondary glaucoma is not common clinically. Only in two instances was increased intraocular pressure encountered. Even though medication has since been discontinued in these cases, no further tension increase has been noted. This infrequency of glaucoma has been observed by others. It has been stated that it is due to the atrophy and fibrosis of the iris and pectinate ligaments (Kirwan³¹). However, two of the sectioned eyes showed depression of the lamina cribrosa, and a diagnosis of secondary glaucoma was made.

Another interesting observation, perhaps associated with the iris atrophy or possibly due to the direct neural involvement in leprosy, was the lack of response of the leprosy iris to atropine. Even in eyes apparently free from synechiae, the poor dilatation obtained from atropine was noteworthy. This fact became especially disconcerting when one tried to get a satisfactory dilatation in cases of iritis.

SCLERA

Leprosy of the sclera appears to be nearly always secondary to limbal involve-

ment and reacts to the inflammation through contiguity of structure. The limbal and conjunctival lepromas were invariably accompanied by episcleral injection. Likewise, in some of the conjunctivitis there was persistent episcleral injection after the instillation of adrenalin 1:1,000. However, one would hesitate to consider these as true cases of episcleritis on the basis of the adrenalin test alone. A leproma of the sclera extending from the 11- to the 2-o'clock position occurred in one case. It gradually receded until an atrophic area resulted. At the present time this area has become a bluish staphyloma, and the condition remains stationary. None of the histologic sections showed infiltration into the sclera proper.

LENS AND VITREOUS

Lens opacities occurred in 29, or approximately 20 percent of cases. In practically every case they developed as a complication of a plastic iritis. One dislocated lens was seen, but this was in a man who had chronic bronchitis with severe paroxysms of coughing. Vitreous opacities were exceedingly uncommon, even in old cases of healed choroiditis. The pathologic change in the lens did not differ from that usually seen in cataracts secondary to inflammation.

EXTRAOCULAR MUSCLES

One case of divergent strabismus was seen, and this was secondary to a central choroiditis. None of the cases studied revealed any outstanding abnormality of ocular motility. Apparently neural involvement of the third, fourth, and sixth cranial nerves must be exceedingly rare if it occurs at all.

THE FUNDUS

The ophthalmoscopic examinations of 50 patients produced entirely negative re-

sults. Among the other cases, 8 showed evidence of old healed chorioretinitis—in 5 it occupied a central position and in 3 it occurred in the periphery. None of the choroiditis seen was in any way typical of a specific disease process.

Three fundi exhibited massive colloidal deposits and three others showed small colloidal deposits throughout the periphery. Venous sheathing was noted in one case. A mild hypertensive sclerosis was recorded in seven cases of West Indian Negroes. Hypertensive sclerosis of retinal arterioles is unusual in Panamanians.

Retinal detachment was observed in three cases; one gave a definite history of trauma whereas the other two suggested leprosy as the cause. These latter two eyes have not been obtained for pathologic study as yet, but a cyclitic membrane may have been responsible for the detachments. Two of the sectioned eyes showed detached retinas clearly associated with cyclitic membranes.

Primary optic atrophy was present in one case, but this was a proved case of central-nervous-system syphilis.

Pallor of the optic nerve in the absence of glaucoma was observed in six cases. The pallor was chiefly temporal, and the vision was rarely better than 20/200. These cases were regarded as residual to a previous optic neuritis. None of the sectioned eyes showed any involvement of the optic nerve. Van Poole found 49 cases of optic neuritis in 206 patients, or 23 percent. It was described as transitory, in association with acute reactions or high tissue allergy, but other posterior-segment lesions were rare.

The frequency of involvement of the posterior segment of the eye has been the subject of a considerable difference of opinion. Neve considers the choroid free from attack except at its anterior attach-

ment to the ciliary body. Trantas found punctate lesions with pigmentary proliferation in the peripheral fundi in a large number of the cases that he observed. He found the retinal lesions in the extreme anterior portion at the ora serrata. They are described as round white spots such as are seen in albuminuric retinitis. Digital pressure was necessary to bring out these lesions. Rubert³² reported changes in 23 percent of his cases. At Palo Seco choroiditis of a nonspecific character was recognized in a little more than 5 percent of patients. Fernández in 250 cases never found the optic nerve involved and only rarely observed lesions of the retina and choroid. De Vincentiis found the retina and choroid normal as far as the ora serrata in 300 fundi examined. Jeanselme and Morax³³ found changes in a leprosy eye in the anterior part of the retina close to the ora and a small nodule lying next to the wall of a terminal arteriole. Gytoku³⁴ studied 30 enucleated eyes histologically and concluded that lesions of the fundi were rare. Huizenga³⁵ and Kirwin examined many leprosy eyes and concluded that practically all ocular leprosy lesions were anterior.

Prendergast emphasized that a relatively large number of eyes in his cases failed to dilate with atropine sufficiently to allow a satisfactory examination of the periphery. This "atropine resistance" has been noted in a similar large percentage of leprosy irides here. However, a subconjunctival injection of atropine, cocaine, and adrenalin frequently induced a prompt dilatation. It was the impression that peripheral synechiae near the base of the iris were often responsible for this poor response to 2-percent topical atropine.

Ophthalmoscopically one fact was outstanding. A comparison of the degree of

involvement between the anterior and posterior segments of the eye in leprosy was striking. Leprosy, characteristically, involves the anterior segment of the eye.

TREATMENT

MEDICAL

As in the general treatment of leprosy, a number of drugs have been applied in ocular leprosy and almost an equal number have been found to be of no genuine usefulness. However, a few therapeutic agents have at least stood the test of time and are indicated in certain leprosy ocular disorders. Treatment is difficult to evaluate, since by the very nature of the disease there are periods of remissions when the patient feels quite well and even fancies that his eyes and sight have improved. Ocular leprosy appears to advance in waves—each wave advancing the disease process just a few steps further until vision is eventually lost.

Since the Colony at Palo Seco is run as any other community, medical treatment is not compulsory. The older patients have been seen by so many different physicians and have tried so many different medications that the general attitude is one of hopelessness or at least resignation. It was only over a period of months that an adequate clinic attendance for ocular treatment was instituted. Coupled with the lack of faith in treatment there is difficulty in getting the patients to carry out instructions over a sufficient length of time for anticipated results. The attitude of my patients often struck me as a general apathy toward drugs but an earnest desire to cooperate with me as a friend.

Nearly all the patients have taken, or are taking, chaulmoogra oil or its derivatives. The oil is expressed from the seeds of *Taraktogenus kurzii*. It is ordinarily given by intramuscular injection,

3 to 10 c.c., or occasionally by mouth in the dosage of 2 drops to 2 c.c., depending on the tolerance of the patient. Mixed ethyl esters of the oil are used regularly, and chaulphosphate (water-soluble chaulmoograte) has been used in a small number of cases for a short time. The beneficial results are apparently transient. Local injections of the ester into nodules about the eyes causes scarification and disappearance of the nodules, such as any other sclerosing solution might perform.

Aniline dyes with and without mercury, serum from cultures, and arsphenamine were without real benefit in leprosy.

Large doses of thiamine chloride injected intramuscularly and given by mouth may be of value in reducing pain in the peripheral neuritis.

In conjunctivitis, especially of the severe purulent type, a 2-percent aqueous solution of mercurochrome appeared to be effective in reducing the discharge and making the patient much more comfortable. There is a general preference for colored medicines among these people and for this reason, perhaps, mercurochrome was used more regularly than clear solutions. A 5-percent sulfathiazol ointment applied night and morning helped to keep the conjunctivitis under control.

It was mentioned previously that the conjunctivitis encountered was probably of nonleprous origin. For this reason it might be expected that any of the reliable medications used for purulent conjunctivitis would be useful.

The leprous keratitides were treated in all stages of development. Five-percent ethylmorphine hydrochloride or 2-percent quinine bisulphate ointment were found to have no effect in improving the cornea or even stabilizing the process. Corneal ulcers, though not commonly seen, respond quickly to the usual treatment. Exposure keratitis due to lagophthalmos was

aided by canthoplasty. Xerosis of the cornea and Bitot's spots near the limbus responded readily to vitamin A.

Sol. thyroxin (Squibb) used locally in drops was reported as giving fair results in clearing corneal infiltrates in 4 of Prendergast's 17 cases, although 11 patients reported having better vision. Similar series were tried at our colony. Although 80 percent reported better sight after 49 days, actual improvement by slit-lamp observations could be seen in but half this number. All of the eyes prior to treatment showed a measurable amount of superficial keratitis and one eye of each patient was kept as a control. The visible amount of improvement was small but so far it has been the most encouraging drug used. It is said to act locally by increasing cell metabolism and tissue repair.

Chronic recurrent iritis was one of the most difficult problems at the colony. In many cases the iris had previously been the site of inflammation and was partially bound with synechiae. Even when visible synechiae were not present atropine worked poorly, as previously mentioned. Scopolamine HBr has but little better effect. It was found that intramuscular milk injections, intravenous triple typhoid, and intramuscular diphtheria toxoid were effective in the order named for the recurrent attacks.

These foreign-protein injections also seemed to exert a beneficial effect on the patient as a whole. Contrary to what I first anticipated, the patients began asking for more injections when they first began feeling twinges of pain in their eyes. The foreign protein lessened the duration of the iritis by at least half. High doses of salicylates were of no benefit in chronic iridocyclitis. Mercury and iodides in the form of mixed treatment caused nodules to ulcerate and the medication was soon discontinued.

Lenses were prescribed when requested by the patients, often with surprising improvement in the visual acuity. Glasses are a great vogue among West Indian patients even when the beneficial effects are scarcely sufficient to warrant their purchase. Photophobia is a common complaint as a result of the tropic glare and the ocular pathologic change; ground dark glasses and eye shades have been advised in all instances. These sun glasses provide considerable relief and may even act as a protective mechanism.

Many forms of medical treatment for the eyes seem to work a beneficial psychic effect on the patient during the time that the ocular disease is not actively progressing. However, as soon as there is a subacute recurrence the patient usually stops his treatment, since to his mind it has made him worse.

Faget, Pogge, *et al.*³⁶ have reported on the use of Promin in leprosy. They found leprous punctate keratitis improved in two cases and observed less frequent attacks of iritis after the use of Promin; improvement in vision occurred in one patient. Promin is being used on a series of patients at Palo Seco at the present time. It would be ideal, of course, to use a drug for leprosy which would inhibit or kill the bacilli. It may prove to be that Promin or another chemotherapeutic compound will act more efficaciously against the disease.

A group of French scientists, who for many years experimented with possible treatments for leprosy, feel that they have at last discovered a probable cure for this disease.³⁷ This research group, headed by Drs. Grimes and Pierre Boiteau, has just issued a scientific report on the successful treatment of leprosy with the use of a new kind of glucose extracted from "hydracotyle asiatic," a wild plant of the carrot family which grows in

Madagascar. As early as 1937 Boiteau and Grimes attempted to use this plant in leprosy, but as the plant's chemical composition was then little known, the extracts that were employed could have proved fatal. Then, in 1939, Dr. Bontemps, who was working in the leprosy research laboratory in Tananarive, discovered a new glucoside which he called "asiaticocide." Less poisonous, "asiaticocide" is insoluble in water, only slightly soluble in alcohol, but can be satisfactorily dissolved in pyridine. After extensive research work Boiteau succeeded in making a solution that could be injected into the blood stream, and further experiments proved highly successful. According to the hypothesis of Boiteau and Grimes, "asiaticocide" acts as a solvent on the waxy part of the microbe. Once this is accomplished the bacillus can be easily destroyed by the human organism itself or by appropriate medication. Remarkable results have been obtained in hospitals. Ocular lesions have been cured in cases wherein the inner chamber of the eye has not been attacked. It has been noted that the nodules and ulcers, which are so characteristic of the disease, yielded readily to the treatment and healed. It is stated that crippled nerve cases require longer treatment, but react favorably to the use of "asiaticocide."

SURGICAL.

Surgery of the leprous eye does not differ from other eye surgery except that one is working with a chronically progressive disease. Therefore, the basic philosophy of the ophthalmic surgeon dealing with leprosy differs to this extent. He is interested in any procedure that will postpone the day of visual loss or may assuage the ocular complaints of his patients, no matter how temporary the relief may be. One cannot afford to

take the attitude of hopelessness and be a good physician among the lepers. Anything but a genuine interest in their plight is quickly detected by these patients, many of whom are unlettered.

Surgery of the lids probably gives the most gratifying results. Secondary to orbicularis paralysis with atony of the lower lids the formation of an ectropion is common. Excessive tearing and macerated lids with exposure keratitis are the usual complications. An ectropion repair, utilizing the Kuhnt-Szymanowski technique, was successfully performed on six lids. All but two have remained in a good state of repair. In these latter two cases the puncta have begun to reëvert due to increasing relaxation of the lower lid. Further removal of skin triangles will reapproximate the puncta. Pinkerton¹² has reported on the successful use of his technique for ectropion repair, which closely parallels the Kuhnt-Szymanowski technique.

Blepharochalasis with a nodule in the most dependent portion has been seen. These are sometimes pendulous to the extent that they interfere with vision. Removal of the redundant skin and re-suturing appears to be sufficient.

Chronic dacryocystitis cases are usually surgical problems. Dacryocystectomy is performed when drainage and irrigation are of no avail. A dacryocystorhinostomy is not indicated, owing to the prevalence of infection in the nasal mucous membrane.

Extreme gentleness is necessary in the removal of the tear sac, since the lacrimal bone may be necrotic. In my first tear-sac extirpation I found the tip of my instruments inside the nasal vault despite what I considered gentle manipulation. An external fistula was formed which later was closed by topical application of 50-percent silver nitrate.

Enucleations were performed in five instances; four in recurrently painful blind eyes and the other in a case of a giant leproma of the cornea. The corneal leproma peeled easily at the line of cleavage but the eye was subsequently removed, since it was totally blind. The sockets would easily accommodate a prosthesis. However, by the time patients have reached this stage the loss of their fingers makes manipulation of a prosthesis impossible and they prefer an eye pad or dark glasses.

Pterygia were successfully transplanted in several instances. Yet, as Pinkerton has so well stated, "there is so much to be done for the patient that pterygia are rarely touched unless . . . they are growing to the point of visual disturbance."

Cataract extraction was performed in three cases. In two cases I waited a year in an endeavor to lessen the chronic iritis as evidenced by posterior synechiae and keratitic precipitates. The iridectomy was done corresponding to the clearest part of the cornea. There was visual improvement in each instance, although far below what one might anticipate from an uncomplicated cataract. A broad iridectomy with attempted release of synechiae was carried out in two other cases. Discissions were done on two patients who had after cataract.

It is of interest to know that the leprous eye withstands surgery well despite a recognizable amount of chronic inflammation. In fact, of the intraocular surgery performed it is believed that most of the eyes now appear to have less inflammation than prior to surgery. It has been previously observed and mentioned that leprous eyes seem peculiarly immune to the ordinary organisms. Questionable aseptic technique often put this to a severe test. There were no postoperative infections in any case.

It was also observed that despite all the blind and phthisical eyes that were seen very few patients complained. Diabolical as it may seem, as long as any sight persisted a chronic recurrent inflammation attacked and reattacked their eyes. Often the phthisical eyes became less painful and less inflamed after all the damage had been done.

It is to be remembered that ocular leprosy has the same course as the general disease, so that palliative measures are the chief resort, at our existing stage of information.

SUMMARY

1. The effect of leprosy on the eye has been studied in 150 cases in Panama.
2. Seventy percent of the patients were natives of Panama, the remainder came predominantly from the bounding countries and the West Indian Islands.
3. Ninety percent of the patients of the leprosarium were found to have ocular involvement.
4. Impaired vision is common in leprosy. Thirteen percent were totally blind

and an additional 41 percent had vision reduced to 20/200 or less.

5. The anterior segment of the eye is by far more frequently involved than is the posterior segment.

6. Superficial punctate keratitis or pinpoint lepromata of the irides are so typical as to be diagnostic of ocular leprosy.

7. Glaucoma is not common.

8. Absolute corneal anesthesia is rare, but relative loss of corneal sensitivity does occur.

9. Prophylaxis for leprosy eyes through protection with dark glasses or goggles is indicated. The factor of protection has been underemphasized in the past.

10. Therapy is largely confined to palliative measures.

11. Solution thyroxin used topically may be of aid in helping to clear corneal infiltrates.

12. The leper withstands surgery of the eye better than one might suspect. Surgery of the lids produces gratifying results.

SUPERFICIAL PIGMENTATION OF THE CORNEA

R. R. BLONDIS, CAPT. (MC), A.U.S.

Pigmentation of the superficial layers of the cornea has not been described frequently in scientific literature and for this reason, perhaps, has been considered rare; whereas pigmentation elsewhere in the body surface has been accepted as a common occurrence. The following observations had their origin during the study of the clinical pathology resulting from the action of chemical-warfare agents on the eyes and are presented for their medical interest and to add to the fund of general knowledge. It is hoped that complete correlation of this subject with that of pigmentation of other epithelial membranes will thus be aided.

Pigmentation of the superficial layers of the cornea has been described in normal eyes in senility, congenital melanosis, after severe infections such as trachoma and keratitis eczematosa, and in avitaminosis A. It was previously our opinion, based on the study of reports of extensive series of cases, that pigmented lines in the superficial cornea were rare.^{1,2} Frequent appearance of such pigmentation following chemical injury stimulated

our search in other conditions and resulted in observing it in several unrelated pathologic states.

The morphologic characteristics of the pigmentation seen have been those of Stähli-Hudson lines, Fleischer rings (as seen in keratoconus), crescents, oblique lines, and amorphous pigment deposits (figs. 1, 2, 3, 4).

The first of these needs no explanation; it was seen in three types described by Vogt (green-brown, ochre-yellow, and colorless). Since these so-called types have been seen to develop from the colorless to the most colorful in the same lesion, without change in shape, we feel that they are the results of the same abnormality and represent merely stages in development.

The Fleischer rings observed have all been incomplete and otherwise exactly as described as occurring in keratoconus.

A search through the available literature revealed no exact reference to the crescents of pigment. These occurred near the inferior corneal limbus but were separated from it by two or three milli-

meters of normal cornea. The superior borders of these pigmented areas were almost horizontal, and the crescents occupied the portion from the lower third to the lowest sixth of the corneas. Individual pigment clusters were contained within the epithelium to a very slight extent and to a far greater one within Bowman's membrane. The surface of the involved cornea was entirely regular. Pillat³ has described pigmented areas so placed and shaped as to resemble the

pigmented crescents herein depicted. He considered these to be melanomata.

The oblique lines have all been identical with Stähli-Hudson lines except that they ran in a vertically oblique direction.

Amorphous pigment deposit is a term used here to describe a group of pigment clusters without discrete boundaries and occurring in the Bowman zone.

In these types of superficial pigmentation the color of the pigment varied from light yellow through green to dark brown.

Figs. 1, 2, 3, 4 (Blondis). Semidiagrammatic drawings of pigmented corneas. Fig. 1, Stähli-Hudson line intercepted by slitlamp beam. Fig. 2, Fleischer ring intercepted by slitlamp beam. Fig. 3, oblique line intercepted by slitlamp beam. Fig. 4, crescent intercepted by slitlamp beam.

All shades were seen, varying with the severity of the pathologic process, its duration, and the individual complexion. In all cases, all other factors remaining the same, in the Negro and the dark-complexioned races the pigmentation was of darker hue and more bountiful. Whenever there was a concomitant pigmentation of the skin the corneal pigmentation (if present) was in direct ratio. Except in the cases of amorphous deposits the reaction was reversible and the pigmentation disappeared when the eye had completely returned to its normal state.

In this study superficial pigmentation of the cornea was found in five types of corneal pathologic change. There can be little doubt that these do not exhaust the conditions wherein it can occur.

Four hundred and fifty-three (453) individuals whose eyes had been burned with the vapor or liquid of mustard gas (dichloroethylsulfide) have been examined. These cases revealed pigmentation of the superficial cornea in 127, or 28 percent. In other chemical burns of the eyes the corneas were not routinely searched for pigment. Therefore such cases are not utilized for statistical purposes in this paper.

Of approximately 3,600 other individuals whose eyes were examined, search for pigmentation of the superficial layers of the cornea revealed it in 71 cases, or 2 percent.

CASE REPORTS

The following reports are typical of the cases in which the pigmentation described was observed.

Case 1. A white man, aged 62 years, was subjected to the explosion of a mustard shell while unmasked. His left eye was severely burned and his right only slightly. After 12 days, examination of the cornea of the right eye with a

microscope showed a typical Stähli-Hudson line. This was colorless; three days later it was ochre-yellow; one week later it was greenish-brown. Three weeks after the injury the line had completely disappeared, and there was no sign of the injury the eye had suffered. The left eye at no time showed corneal pigmentation. Despite the severity of the burn of this eye no vascularization of the cornea developed and no iris changes or keratic precipitates were seen. The pathologic change was essentially an infiltration of the cornea below Bowman's membrane which resulted in a "snow-flake" stroma.

Case 2. A white man, aged 26 years, was subjected to the same explosion and suffered a severe burn of the left eye and a mild one of the right. The findings were the same as in case 1 except that the pigmented line ran in a vertically oblique direction in several widespread areas of the exposed portion of the cornea of the mildly injured eye. The severely injured eye followed the same pattern as the severely injured eye described in case 1.

Case 3. A Negress, aged 32 years, worked, unmasked, in the immediate vicinity of a mustard-gas spill. Her right eye was moderately burned and her left severely. Eight days after the injury an incomplete Fleischer ring was visible in the cornea of the right eye. This remained for three months. All other signs and symptoms resulting from the injury disappeared about two weeks earlier. For the first three months following the injury to her severely burned eye there was no evidence of corneal pigmentation. After this time she developed pannus degenerativus of this cornea and with it appeared an influx of brown pigment as far as the vertex of that membrane. This coloration was amorphous, patchy, and followed the approximate course of the invading blood vessel. At this date (six

months after the injury) the vascularization and the pigmentation are still present.

Case 4. A Negro, aged 42 years, was exposed on two successive days to the vapor of mustard gas. On the third day he developed a typical keratoconjunctivitis⁴ of both eyes. Two days later, as the signs and symptoms receded, there was noted an area of greenish-brown pigment, crescent shaped, occupying the lower third of the cornea. Examination with the microscope revealed pigment following slightly irregular lines, densely packed, separated from the limbus by an unpigmented zone about 2 mm. wide. The pigment was limited to Bowman's membrane. About eight days after the injury, although the signs and symptoms had almost disappeared, the upper border of the pigmented crescent had become demarcated into a distinct line resembling a Stähli-Hudson line but continuous with the crescent-shaped area of pigment below it. Seven weeks after the injury and six weeks after all other signs and symptoms had disappeared there was no sign of corneal pigmentation.

Case 5. A Negress, aged 37 years, suffered a burn of the cornea of the left eye from white phosphorus. This resulted in an indolent ulcer at the site of the injury. About three weeks after the burn, the injury had been converted into an epithelized, nonstaining, depressed facet, and at this time its base became infiltrated with a yellowish-brown color. This pigmentation was limited to the burned area in Bowman's zone and increased in intensity for one week after it first appeared. Eight weeks later the depressed facet had been filled in from below and was nebulous. At this time the pigmentation was sufficiently diminished in amount to make it barely visible with the microscope.

Case 6. A man, Mexican-born, aged 28 years, had bilateral vascularized pterygia that encroached on his corneas for approximately 4 mm. He was unaware of their presence. Both corneas showed typical Stähli-Hudson lines.

Case 7. A white child, aged 6 years, was first seen with a solitary phlyctenule of the cornea of the left eye. There was no pigmentation of the superficial cornea. About two weeks later there were multiple phlyctenules and encroaching vascular fasciculi. At this time one of the therapeutic agents used was a 0.1-percent solution of epinephrine hydrochloride.⁵ Five weeks after the onset of the disease the entire cornea was traversed by superficial blood vessels. At this time there first appeared a colorless dehiscence corresponding to a Stähli-Hudson line in location and form. Within two days this line was colored greenish-brown. The vascularization of the cornea and the pigmented line are still present although it is approximately four months after the onset of the illness.

Case 8. A white man, aged 28 years, was first seen with severe, acute iridocyclitis, hyphema, hypopyon, and secondary glaucoma of the right eye. The cause of the inflammation was undetermined. He was treated with the usual local medication and typhoid vaccine intravenously. Two weeks after his illness started the intraocular pressure was within normal limits, there was no blood nor other cells in the anterior chamber and all signs of inflammation were minimal. At this time a typical Stähli-Hudson line was first seen. It was ochre-yellow in color and remained visible with the microscope for five weeks. All other signs of the inflammation had disappeared one week before this except two minute posterior iris synechiae.

DISCUSSION

Most frequently, this corneal discoloration occurred in eyes which were burned with mustard-gas liquid or vapor. It was a frequent finding and disappeared during the stage of healing, which may be prolonged many months if the injury has been caused by the liquid.⁶

It has been a common observation that long contact with the vapor of this vesicant, even though insufficient to cause injury, has resulted in progressive pigmentation of the exposed skin; but it has not been observed in either the conjunctiva or the cornea. This pigmentation is considered to be a response to chemical irritation, a phenomenon long ago observed.⁷

It is interesting to note that when the corneal burn from mustard gas has been severe this pigmentation has not been observed except when the injury to the cornea resulted in vascularization of that membrane. Redslob⁸ found that when the achromogenic cornea is vascularized it develops the potentialities necessary for the elaboration of pigment. When the injury to the cornea penetrated beneath Bowman's membrane no pigmentation of the cornea was observed. When the corneal injury had been deep enough to cause inflammation of the iris with keratitic precipitates these became pigmented quickly.

Pigmentation of the superficial cornea in cases of abrasion in the absence of a foreign body occurred in this series. Here the pigment lay within Bowman's zone in the area of injury and occurred only during the stage of healing. Infection did not need to be present to induce this phenomenon. Staining with 1-percent cresyl-blue solution revealed that these corneas had dilated lymph spaces. The mechanism here was probably the same as that in chemical injury of the cornea. Here too

the injury causing a pigment response did not extend beneath Bowman's membrane.

As has already been pointed out, yellowish-brown pigmentation of the superficial layers of the cornea in keratitis eczematosa⁹ has been observed during this study. The pigment appeared shortly after the vascularization of the cornea, was superficial (within Bowman's zone), yellow to brown in color, and disappeared with the disease. In this condition the pigment existed as Stähli-Hudson lines and also within the maculas resulting from ulcerated phlyctenules to which vascular fasciculi had extended. It is noteworthy that one such case was treated with a solution containing 0.1-percent epinephrine hydrochloride over a period of several months (case 7). Loewenstein⁵ reported that the long-continued use of adrenalin as drops can give rise to pigmented nodules on the conjunctiva. Further, he produced this experimentally.

The nature of the pigment occurring in the cornea has been the subject of some speculation but of little investigation. The likelihood that this pigment is melanin is supported by the similarity between the crescents of pigment herein described and the accumulations of pigment reported by Pillat and by him considered to be melanomata. In addition, some of the pigment seems to be identical in appearance with that described by Meesmann¹⁰ within the cells of the corneal epithelium in Addison's disease. Further, the greater amount of pigmentation in the superficial cornea in Negroes than in whites with the same or similar pathologic conditions speaks in favor of melanin.

To this fact, should be added the relationship of the corneal pigmentation to that occurring in the skin. In mustard-gas keratitis, there occur several of the types of superficial pigmentation of the cornea herein described and not infrequently a

pigmentation of the skin that is clinically indistinguishable from melanosis. When it is recalled that the conjunctiva is but a modified skin and the corneal epithelium merely an especially adapted epithelial layer of that membrane, this concomitance takes on special significance. No report in the literature has shown the presence of melanin or its precursors in the urine of individuals suffering from such exposure. We have attempted to find such pigment in the urine and have been unsuccessful.

Duke-Elder¹¹ describes the migration of chromatophores from the stroma of the uvea into the ciliary muscle and the inner layers of the sclera, whence they sometimes travel along the perivascular channels to appear subconjunctivally and within the loose episcleral tissue associated with vessels and nerves. The close relationship between the conjunctiva and the corneal epithelium has already been mentioned.

Redslob⁸ found that some of the deeper cells of the conjunctiva covering the caruncle were potential melanoblasts which became deeply pigmented on oxidation, and further demonstrated the presence of potential melanoblasts in the region of the limbus. In addition, it is known that the caruncle is frequently pigmented during Addison's disease. Therefore, it seems quite likely that the limbus forms a barrier to the passage of the melanin from the conjunctiva to the corneal epithelium despite the close relationship between them. These melanoblasts within the deeper layers of the limbus contain a colorless substance that is converted into melanin in the presence of the oxidizing ferment dioxyphenylalanine (dopa). The barrier at the limbus may be physiologic, physical, or chemical, and during the pathologic process may be neutralized to permit the migration of

these cells into the corneal epithelium. There may well be a chemotaxis that stimulates migration of cells along the corneal lymph channels, which have been demonstrated with intravital staining to be widely dilated following chemical irritation of that membrane.

Some investigators have stated that the pigment is derived from the blood, and, indeed, Moncrieff¹ has shown in one reported case that it was hemosiderin. There is little evidence to support this idea in the cases here reported. However, the actual demonstration of hemosiderin by Moncrieff within the cornea must be accepted as more accurate than mere observation. According to her conception the blood pigment diffuses down from the upper limbus through the intercellular spaces of the corneal epithelium.

Stähli¹² postulated that the pigment was derived from the alkali-hematin present in the tear fluid and the pooling of that fluid in the inferior cul-de-sac caused the imbibition of the pigment into the corneal epithelium. There is no absolute evidence to support this hypothesis.

All investigators are in agreement concerning the development of the Stähli-Hudson line. There occurs a tension of Bowman's membrane that is most marked at the meeting point of the upper and lower lids during the winking reflex. This results in either a degeneration or tear in that membrane along that line, and is intensified by the mechanical action of the lids. The dehiscence thus formed is demonstrable with the slitlamp and corneal microscope, when using a 1-percent solution of cresyl-blue stain in normal eyes of some middle-aged and elderly individuals. It is this dehiscence that is responsible for the colorless type of Stähli-Hudson line described by Vogt. If the pigment described is melanin it is deposited here through the migration of

melanoblasts along the intracorneal lymphatics. At this line it is assumed that the colorless pigment-bearing cells are converted into colored, pigment-bearing cells and become temporarily fixed. It is more difficult to comprehend that the diffusion of hemosiderin to this line is possible in the absence of any trace of its path, although Moncrieff found that histologically actual pigmentation was much more extensive than that seen clinically.

The formation of the Fleischer rings is similar. The lesion lies in Bowman's membrane and the pigment therein occurs in the same manner as in the Stähli-Hudson line. The only difference is in the location of the original stress or trauma to Bowman's membrane and this depends on the area of maximum injury to the cornea.

The oblique lines within the cornea that occur also in Bowman's zone are undoubtedly produced in like manner and their position and direction are results of trauma in varying areas and directions.

The explanation for the formation of the crescent of pigment seems to agree with the hypothesis of Stähli who considered the pigment to be an iron derivative from the alkali-hematin of the tears. Certainly the pooling of the tears in the inferior cul-de-sac could produce such a formation of pigment, provided that the pigment could be imbibed by the corneal epithelium. This does not explain why the greatest amount of the pigment is in Bowman's zone and not within the epithelial cells themselves. It seems more likely that this area is merely a dense arrangement of lines produced in the manner suggested above and that the pigmentation occurs in a like manner.

SUMMARY AND CONCLUSIONS

1. Pigmented lines in the superficial

layers of the cornea are not rare in our experience. They were seen in 28 percent of 453 individuals whose eyes were burned with mustard gas and in 2 percent of 3,600 other cases in such conditions as white-phosphorus burns, pterygia, eczematous keratitis, and iridocyclitis.

2. Eight case reports are presented which represent the abnormalities in which this pigmentation has been observed and the various morphologic characteristics of the pigment.

3. Stähli-Hudson lines, Fleischer rings, oblique lines, and pigmented crescents are the result of pigmentation of dehiscences in Bowman's membrane and represent merely the same type of injury in different locations within this membrane.

4. Observation of the cases reported here favors the concept that this pigment is melanin, although histologic and chemical studies in a single case demonstrated that the pigment in that case was hemosiderin. Conclusive evidence of the character of the pigment is not yet available.

5. If a corneal burn extends deeper than Bowman's membrane, no pigmentation occurs unless the superficial cornea becomes vascularized.

6. In the presence of the abnormalities already described, the melanin content of the conjunctiva at the limbus is increased, but this pigment does not invade the cornea unless damage has been done to that membrane. This suggests that a barrier to the cornea exists at the limbus which is destroyed when that membrane is injured.

7. Most observers agree that the pigment reaches the superficial layers of the limbus and the most likely pathways are the lymph spaces in the cornea, which can be demonstrated under certain conditions to be widely dilated.

GLIOMA OF THE OPTIC NERVE*

MAX MANNHEIMER, M.D.

Jackson Heights, New York

In a review of the whole literature in 1912, Hudson¹ mentions not more than 182 cases of glioma of the optic nerve. Katzin² recently reported a case of glioma of the optic nerve with discussion of the occurrence, symptomatology, course, and pathology, and pointed out that this lesion had been described not more than 300 times in the literature up to the present. This rare occurrence seems to be reason enough to add another case of such a neoplasm that has just come under observation.

CASE REPORT

E. F., a colored girl aged eight years, came to my office on March 3, 1945. Her father stated that the right eye had been swollen for six weeks, the swelling gradually increasing. There had never been any inflammation of the eye; nor was there a

history of an injury. The child had not complained of pain at any time. No convulsions or other signs had been noticed. An optician or optometrist had provided her with glasses one month ago.

The child had never been seriously ill.

The general aspect of the patient was good. She was well nourished and seemed to be healthy. Her answers revealed normal mental qualities.

Both eyes were white, without irritation. There was marked proptosis of the right eye, with some restriction of the movements to the extreme right and left. Tension was good in both eyes.

Right eye: There was a definitely increased resistance to backward pressure of the eyeball. No masses could be felt around the globe. The pupil was fixed to light, dilated, and reacted well consensually. Vision was nil.

The lower portion of the disc was swollen, covered with a mass of inter-

*From the Ophthalmological Service of Dr. R. K. Lambert, The Mount Sinai Hospital.

twining small and large blood vessels, partly newly formed. This mass extended out into the vitreous to a height of about 6D. As did also the adjacent lower part of the retina, which was grayish and showed dilated and tortuous vessels. There was no detachment of the retina.

The *left eye* was normal in all respects, vision being 20/20 with a +2.5D. cyl. ax. 90° lens.

The tentative diagnosis was: Tumor of the optic nerve.

On the basis of diagnosis the patient was referred to the Mount Sinai Hospital,

which was approximately twice the size of the left (fig. 1). There were no demonstrable abnormalities of the orbit or sella turcica. X-ray studies of the abdomen and of the long bones revealed no evidence of metastases. An electroencephalogram was normal.

The differential diagnosis between neoplasm of the orbit and tumor of the optic nerve was not difficult, for the main symptoms suggesting the latter were present; namely, nonpulsating, slowly progressive proptosis straight forward, light limitations of movements, early visual failure,

Fig. 1. (Mannheimer). Roentgenogram of the skull showing the enlargement of the right optic foramen.

where the ocular findings were completed by exophthalmometry. The readings were: R.E. 22, L.E. 16 at 98 mm. The width of the papebral fissure was: right, 10 mm.; left, 7 mm.

The field of the left eye showed a slight limitation medially and in the lower field.

Transillumination could not be effected because of poor coöperation.

The general medical examination revealed no pathologic findings. Wassermann reaction was negative. There were no signs of tuberculosis. An X-ray study of the skull showed a considerable enlargement of the right optic foramen,

papilledema, and, perhaps as the most important symptom, enlargement of the optic canal.

Since the intracranial part of the optic nerve was unquestionably involved, Dr. Ira Cohen was consulted, who suggested intracranial section of the nerve prior to enucleation. He proceeded as advised by performing a craniotomy on March 30th.

Operation. On the right side, a Frazier type bone flap was turned down. Before opening the dura through a nick in it, a brain needle was passed into the anterior horn of the right lateral ventricle. This allowed the escape of an estimated 10 c.c.

of spinal fluid. The dura was then opened by an incision just above the bone margin along the temporal and frontal portions. The frontal lobe was elevated. The olfactory nerve was identified and freed from this attachment. Further retraction exposed the right optic nerve. For a little over one half of its distance from the

anteriorly, the flap was replaced, the anterior inferior burr hole was filled with a mixture of bone dust and bone wax, and the scalp was replaced and sutured with two layers of silk.

The child stood the operation very well. Nevertheless, a transfusion was given, beginning at about the middle of the operation.

The postoperative course was uneventful.

The microscopic picture of the resected nerve was described by Dr. Globus as follows:

Section stained with hematoxylin and eosin shows the tissue to be for the most part broken up into small lobules or compartments, but with fairly well-developed connective-tissue trabeculae. Within each of these compartments, there are many cells recognizable mainly by the incorporated nuclei. The latter are variable in size and outline, the majority, however, being oval and fairly rich in chromatin. The nuclei are supported by a syncytium of cytoplasm material which in places is highly vacuolated and in other parts indicates the reticular nature of the cells. In all probability these cells are glial in character. In some compartments the nuclei are much denser than in others, and in some are exceedingly few. Diagnosis: Glioma of the optic nerve (Schwannoma).

On May 1st a second operation on the child took place. Dr. Lambert performed an enucleation with extirpation of the optic nerve. Its isolation from the surrounding tissues within the narrow orbit was tedious. However, working along the nerve in a proximal direction, he was able to resect the entire nerve. It was cystlike, thickened, the diameter of the most enlarged site being approximately 15 mm. The tumor was entirely confined to the optic nerve, with no spreading to the orbital tissues (fig. 3).

Fig. 2. (Mannheimer). Operative field sketch showing the tumor of the right optic nerve before and after resection.

optic foramen and the chiasm, it was very much swollen, probably three to four times the normal diameter. It was also somewhat knobby (see figure 2, drawn during the operation by Alfred Feinberg).

With the trigeminal sharp hook, the nerve was divided close to the chiasm. Then, with the cutting loop, it was removed in two sections, flush with the optic foramen. There was a little troublesome bleeding from the cut in the nerve, which was coagulated. It is judged that not more than 1 mm. of the nerve was left proximate to the chiasm, and this appeared normal.

Bleeding having been completely controlled, the dura was tightly closed, a Penrose drain was let out from the extradural space through a stab wound pos-

Fig. 3. (Mannheimer). Enucleated globe with resected optic nerve.

The postoperative course of the second operation was uneventful. The child is at present (six weeks later) in good general health. Her left eye is normal, especially the fundus, and she has the same vision as when seen first.

The prognosis of this case is favorable. As gliomas do not metastasize and do not perforate the sheaths of the nerve, it may be assumed that the child will remain well. The decisive factor is the involvement of the chiasm, but an operation is not feasible. With further infiltration of the chiasm there will follow blindness of the other eye, sooner or later, and from pressure on the centers of the diencephalon serious disturbances of the vegetative system will ensue and finally death. Whether X-ray therapy can be of lasting benefit, is doubtful. Duke-Elder goes so far as to call roentgen therapy "of little significant value." On the other hand it is well known that gliomas of the optic nerve have a slow growth; von Hippel³ mentions a patient under his observation, who was absolutely well after an incomplete extirpation 20 years previously.

DISCUSSION

The case herein presented, so far as symptomatology, therapy, and pathology are concerned, is to be regarded as rather typical. With reference to the differential diagnosis it has been pointed out that all symptoms of an optic-nerve growth were

present. They are similar to those of an orbital tumor, the three classical symptoms of which were established by von Graefe⁴ as early as in 1864; namely, proptosis, disturbance of the motility of the globe, and visual deterioration. The displacement of the globe in tumors of the nerve is usually directly forward or approximately so, showing slow progress. The motility of the globe is less impaired than might be expected from the proptosis. This is different in tumors of the sheaths, when the orbital muscles and nerves become infiltrated; then ocular movements become considerably restricted.

The visual acuity usually deteriorates early and rapidly. For this reason diplopia by displacement of the globe does not occur, contrary to what occurs in the case of orbital tumors, where this symptom is very common.

The tendency of the growth of the tumor is directed back toward the brain; it may, as Duke-Elder puts it, "cause a hypermetropic refraction by pressure upon the posterior pole of the eye. More commonly the effects of obstruction of the circulation are seen—papilledema, and eventually secondary atrophy are relatively common." In my case there was both a hyperopia of 6D. and a partial papilledema. There was no atrophy of the disc; this agrees with the fact that in most cases the degree of visual defect is out of all proportion to the ophthalmoscopic signs. One of the most important changes caused by the proximal growth of the tumor—namely, the enlargement of the optic foramen—was present. Thus, an involvement of the intracranial part of the nerve by the neoplasm was out of the question. As symptoms of extension into the chiasm and into the brain were absent, the therapeutic procedure was a first operation—resection of the intracranial part.

of the affected nerve—and a second operation—the extirpation of the intra-orbital portion. The ophthalmoscopic findings were such as led to the assumption that the posterior pole of the globe was involved or at least its immediate vicinity, so that the eyeball had to be sacrificed. Since this was not the case a resection of the orbital part of the nerve could have been performed by means of the Kroenlein operation, with preservation of the globe, done for the first time in a case of optic-nerve tumor by Braunschweig⁵ in 1893, or by opening the orbit from the conjunctiva with temporary tenotomy of the recti internus and superior.

The anatomic nature of tumors of the optic nerve remained controversial for a long time with much confusion as to the terminology. Since the classical papers of Hudson in 1912 and of Verhoeff⁶ in 1922 the anatomic picture has been clarified. These investigators pointed out that "the essential feature in the production of these tumors is an overgrowth of glial tissue" and that "gliomas are the only primary intraneural tumors of the optic nerve that have been observed." They differ from each other only quantitatively, depending on the presence of various glial elements in different proportions and arrangements. These true gliomas are related to those occurring in the brain and, this should particularly be stressed, have no relation to the common malignant tumors of the retina popularly called "glioma."

As has been mentioned, all optic-nerve tumors, whether they originate from the nerve proper or from its sheaths, are rare, the gliomas being the most common. Reviewing large series of treated patients, Collins and Marshall, as also Verhoeff, came to a ratio of tumors of about 1:176,000 (Davis⁷). With regard to the age of the patients, most gliomas were found in

children under five years of age. Tumors of the nerve sheaths—endotheliomas of Hudson—occur later, most of them after the age of 30. Most observers agree that the female is more frequently affected; Lundberg,⁸ however, could not find this difference in his cases.

The vast majority of the gliomas arise from the intraorbital portion of the optic nerve. Their growth is fairly characteristic. It is almost invariably slow, although temporary periods of rapid growth have been reported. They advance by direct extension along the intraneural portion of the nerve and, as has been mentioned do not penetrate the sheaths, so that as a rule a diffuse and uniform hypertrophic swelling, sometimes of a spindle-shaped appearance, is produced.

The glial tumor starts with an abnormal proliferation of the normal adult type of neuroglia (Davis). The neoplastic tissue permeates the intraseptal spaces, with occasional invasion of the septa. They usually are enormously thickened, made up of collagenous fibers. This collagenous hyperplasia is regarded as reactive in nature and secondary to the gliomatous process in the nerve. This is particularly obvious when a glioma occurs in general neurofibromatosis or von Recklinghausen's disease. By the growth of the glial tissue the nerve fibers are spread apart, stretched, and compressed, so that they become demyelinated at an early stage, which means loss of vision. The intermingling of secondarily proliferated mesothelial cells of the arachnoid with the neuroglia cells produces a complex histologic structure, the precise nature of which is difficult to interpret. The neoplastic glial cells are uni- or bipolar spongioblasts in type, are long and spindle-shaped with oval nuclei and processes at each end. From an embryologic point of view it will be understood that

these cells are identical with the characteristic cells of this type of tumor that is found in the brain.

SUMMARY

A somewhat typical case of glioma of the optic nerve has been presented with

discussion of the diagnosis, operative treatment, and biopsy. The favorable prognosis has been stressed after extirpation of the neoplasm *in toto*. Two operations at different times proved to be the therapy of choice.

THE RELATIONSHIP BETWEEN LIGHT ADAPTATION AND DARK ADAPTATION AND ITS SIGNIFICANCE FOR APPRAISAL OF THE GLARE EFFECT OF DIFFERENT ILLUMINANTS*

ERNST SIMONSON, M.D., SAMUEL S. BLANKSTEIN, M.D.,
AND EBEN J. CAREY, M.D.

A precise knowledge of the characteristics of adaptation of the eye to light is of importance for several reasons other than that such a fundamental process should be as clearly understood as possible. It will be demonstrated in this communication that serious errors will result in the determination of dark adaptation if account is not taken of the initial adaptation to light. Accurate determinations and the understanding of the effects of glare are not possible without a knowledge of the adaptation to light.

Data on light and dark adaptation on 10 individuals will be presented. Particu-

lar emphasis has been placed on the relationship between the rates of light and dark adaptation, the relationship between the dark-adaptation time and the initial light-adaptation threshold, the relationship between brightness and length of exposure to the rate of light and dark adaptation, both daily and interindividual variation, and the effect of spectral distribution.

In contrast to the great number of publications on dark adaptation which have been published during recent years, the problem of light adaptation studied by determination of brightness thresholds has attracted considerably less attention. Several publications have presented data on the influence of brightness level on light adaptation,¹⁻⁴ but we know of only one paper⁵ wherein the speed of light adapta-

* From the Laboratory of Physiological Hygiene, University of Minnesota, Minneapolis, and Marquette University, Medical School, Milwaukee.

tion has been investigated by varying the duration of light exposure at a constant brightness. However, the time intervals used were too long to determine details of the course of light adaptation, especially in the early phases. These data have established that, in general, light and dark adaptation follow opposite trends. With increasing exposure time or higher brightness, light adaptation proceeds faster and dark adaptation more slowly. For this reason, light and dark adaptation might be looked upon as corresponding catabolic and anabolic processes expressed in terms of concentration of photosensitive material, as is the case in Hecht's formula.⁴ While there is no doubt of the opposite trends of light and dark adaptation, their mutual relationship has not yet been thoroughly studied. Some discrepancies between light adaptation and dark adaptation are apparent in the material of Hecht *et al.*¹ and of Müller⁵ as well as in our own investigations on the light penetration through the eyelids.⁶

METHOD

Due to the numerous variations of time intervals and brightnesses in our experiments, resulting in up to 40 exposures in one single testing series, Blanchard's³ method for determining the instantaneous thresholds after light exposure was not applicable. Instead, we used an approximate method, measuring the threshold about five seconds after the light exposure in successive experiments with increasing light-exposure duration; this we define as the relative light-adaptation threshold. Thus, we obtained a curve of threshold values somewhat below the instantaneous threshold but closely related to it. Variation of ± 1 second in the time of the first reading produced only minor differences of the relative light-adaptation threshold, hardly exceeding the experimental error (± 5 percent).

After the first reading, which is an index of light adaptation, the progressive dark adaptation was measured until the value of 0.05 millifoot candles (M.F.C.) was reached. This value includes full cone adaptation and the first (rapid) segment of rod adaptation after longer exposure times or higher brightness. After short exposure time, the dark adaptation is so rapid that cone and rod adaptation are not clearly separated.

Newton's instrument was used, in which the brightness of the test patch (of one-third degree, five degrees above the small red fixation point), is changed by varying the angle of a light beam illuminating the test patch. Thus, the color of the test patch does not change at different brightness levels. In order to investigate the effect of spectral distribution, ordinary frosted incandescent lamps (A) were compared with a new illuminant (B) with reduced radiation at both ends of the visual spectrum. More detailed information about the spectral distribution of this illuminant (Verd-A-Ray) is given in former papers.^{7, 8} On each experimental day, both the illuminants—A (ordinary frosted lamps) and B (Verd-A-Ray lamps)—were compared at the same brightness level. For light exposure, the subject viewed, from a distance of six inches for lamp A, a frosted glass plate placed in front of a box and illuminated from behind by a centrally fixed lamp. The different levels of illumination were obtained by using different bulbs (25, 60, 100, and 200 watts), corresponding to 125, 200, 620, and 1,050 F.C. at the level of the observer's eye. Since the brightness of illuminant B was about 25 percent lower in our arrangement, equal brightness for both illuminants was obtained by shortening the distance to the frosted glass plate for illuminant B. Since the visual field was already very large at the distance of

six inches from the frosted glass plate (used for lamp A), its enlargement at the closer distance from lamp B is of no consequence. For the brightness levels of 125, 200, and 620 F.C. the following exposure times were used: 0.5, 1, 2, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 100 seconds. The series of consecutive exposures was terminated as soon as the limit of the instrument (10 M.F.C.) was reached. Sometimes in order to determine the time necessary to reach 10 M.F.C. more accurately, intermediate exposure times were given. Nevertheless, the light adaptation time for 10 M.F.C. cannot be determined with the same accuracy as the thresholds below this upper limit. For the brightness level of 1,050 F.C. much shorter exposure times were used (0.5, 1, 2, 3, and so on seconds).

Three well-trained and seven less-well-trained subjects were used, the latter only for the 200-F.C. brightness level. These subjects represented the extremes of fast and of slow dark-adaptation times in a former series of 32 subjects.⁷

The readings were repeated for all or most exposure times. All light exposures were given as soon as the subject had reached the threshold value of 0.05 M.F.C. The relative light-adaptation thresholds agreed in most duplicate readings within 5 percent of the mean. If the discrepancy was greater the same exposure was repeated for a third time. The dark-adaptation-time readings (time to reach the threshold of 0.05 M.F.C.) agreed within ± 10 percent, greater discrepancies being due to interference of afterimages.

In the three trained subjects the same arrangement was repeated on four to six different days with a reversed order of lamp A and B. In the seven less-well-trained subjects the experiments were repeated on two different days.

RESULTS

Course of light adaptation and of dark adaptation. Table 1 shows the average results of relative light-adaptation thresholds for exposure durations between

0.5 and 50 seconds, for the purpose of general orientation as to the magnitude of changes. The longer exposure times at the 125- and 200-F.C. brightness levels

are omitted. The figures are averages of 4 to 6 experiments in subjects S. S., E. S., and S. B., and averages of 14 experiments on 7 subjects in the last two lines. It will be noted that the wide threshold range from 0.05 to 4 or more M.F.C. is passed through within less than 0.5 second, while the further increase is much slower. Table 2 shows the corresponding average values of the duration of dark adaptation necessary to reach the level of 0.05 M.F.C.

Fig. 1 (Simonson, Blankstein, and Carey). Average light-adaptation curves in three well-trained subjects.

The average curves of light adaptation in most instances show a sigmoid shape, except at the highest brightness of 1,050 F.C., where the speed is too rapid for our intervals of exposure durations. Figure 1 shows the average light-adaptation curves for 620 F.C. with subjects E. S. and S. S., and 125 F. C. for subject S. B., because his speed is of approximately the same order at this lower brightness level. The curves were obtained with lamp B; however, there were no differences between lamps A and B in this

respect. For a duration of exposure between 2 and 5 or 10 seconds the light-adaptation speed is slower than before or after. The shape of the curves is, of course, largely determined by the logarithmic abscissa of the exposure time, but the sigmoid contour is also present with linear coordinates. Figure 2 shows a sigmoid contour also in the corresponding dark-adaptation time, due to a less-pronounced

Fig. 2 (Simonson, Blankstein, and Carey). Average dark-adaptation curves for three well-trained subjects.

increase of dark-adaptation time when the duration of exposure was between 2 and 5 seconds.

The comparison between tables 1 and 2 and of figures 1 and 2 shows a general relationship between light and dark adaptation, in that with increasing exposure time and brightness the relative light-adaptation threshold increases, whereas the dark-adaptation speed decreases. Furthermore, with lamp B light adaptation is slower, whereas dark adaptation is faster at the longer exposure times.

This apparently good agreement does not hold, however, for the details of the course of light and dark adaptation. In the single experimental series we found frequently that in two or more consecutive

exposures of increasing durations the thresholds of light adaptation or the dark-adaptation time remained the same. Irregular increase of the threshold with increasing duration of exposure was present in almost all experiments, as is also revealed in the sigmoid contour of the average curves.

The frequency of plateaus was greatest at the lower illumination levels of 125 and 200 F.C. (in 12 out of 20 experiments with subjects S. S. and in 12 out of 15 experiments with E. S.). In subject S. S., the plateaus (mostly of only two consecutive exposure durations) occurred between 1 and 5, rarely 10, seconds' exposure time, corresponding to threshold values between 5.5 and 7.0 M.F.C. In subject E. S., the plateaus were, in general, of longer duration, up to four consecutive exposure times, corresponding to threshold values from 5.2 to 7.2 M.F.C. Rarely were plateaus observed at higher threshold values or longer exposure times. At 620 F.C. and 1,050 F.C. brightness, S. S. showed no plateaus, whereas there were plateaus of somewhat shorter duration in 6 out of 12 experiments with subject E. S., at thresholds between 8 and 9 M.F.C. No plateau was observed at 1,050 F.C. The plateaus occurred with both illuminants, A and B. Subject S. B., who had a much faster light-adaptation speed, showed no plateaus. The seven less-well-trained observers also showed no plateaus. Plateaus were observed for the total dark-adaptation time for two or more consecutive exposures and were even more frequent than those of the light adaptation; they were present in several experiments with S. B. and also in the seven less-well-trained subjects. Sometimes the plateaus of light and dark adaptation coincided in time, but often they did not.

In Müller's series there was a steady increase of the relative light-adaptation

TABLE 3

COURSE OF LIGHT AND OF DARK ADAPTATION IN SINGLE EXPERIMENTS

threshold (first readings) up to 40 minutes, even sloping up from 20 to 40 minutes' exposure, while the dark-adaptation time to reach 3 different threshold values (0.42, 0.047, and 0.005 Millilux) remained practically constant from 10 to 40 minutes' exposure time. A similar discrepancy was found in several experiments with S. S. (table 3), but was most pronounced in subject Dy, who had the fastest adaptation time. In subject E. S., the opposite tendency of excessive increase of dark-adaptation time at the higher threshold values was frequently observed: two typical experiments are shown in table 3. Table 4 shows a plateau of dark adaptation with increasing light adaptation in subject S. S. at shorter exposure times than those in table 3, and the opposite phenomenon (plateau of light adaptation, steady increase of dark-adaptation time), in subject E. S. Sometimes the plateau of dark-adaptation time and light threshold begins simultaneously, but terminates earlier in either one (table 4).

and exposure duration on light and dark adaptation. From the average curves of light and dark adaptation the light-adaptation time (seconds) necessary to reach 5, 6, 7, 8, 9, and 10 M.F.C., and the corresponding dark adaptation time (seconds) necessary to recover the level of 0.05 M.F.C. were determined by graphic interpolation. The results for the four brightness levels and lamps A and B are shown in table 5, the left side representing speed of light adaptation, the right side representing the corresponding speed of dark adaptation.

The increase of the speed of light adaptation with brightness is obvious. However, the recovery time (cone dark adaptation, right side of table 5) for a given threshold is not uniform, but depends on the conditions of exposure duration or brightness under which the given threshold has been obtained. In general the recovery time for a given threshold increases with exposure duration and consequently decreases with brightness, although a few minor exceptions are noted. Since increasing brightness at constant exposure time would prolong the

Comparison of the effect of brightness

dark-adaptation time, it is obvious that the effect of increased brightness is over-compensated by the shortening of exposure duration. The duration of exposure appears to be a more important factor in regard to dark-adaptation time than the brightness level of light exposure.

In order to evaluate, in regard to light adaptation, the relative importance of exposure duration versus brightness, the product of duration and brightness (F.C.-seconds) was calculated for the various

combinations of exposures and brightness levels. These values were compared at the following F.C.-seconds: 200, 620, 1,240, 3,000, 6,200, and 10,000. Table 6 shows the exposure time for each brightness level necessary to attain the same value of F.C.-seconds. For this comparison, values with lamp A at 10 F.C. were available from another study⁶ up to the value of 3,000 F.C.-seconds. At the higher values of 6,200 and 10,000 F.C.-seconds lamp B was used for comparison because of the

slower light adaption; with lamp A no value at 10,000 F.C.-seconds was available. Most threshold values in table 6 are direct readings, which are preferable even if there are minor differences in the F.C.-seconds values obtained. In a few cases (marked with *), the threshold values were interpolated. The threshold values are in general higher at both ends; that is, at the longest exposure time with lowest illumination level and at the shortest ex-

Interindividual discrepancies between light- and dark-adaptation speed. Table 7 shows the light- and dark-adaptation speed of seven subjects, calculated for thresholds from 4 to 10 M.F.C. The values are averages of two determinations made on different days. At 10 M.F.C. threshold, the light-adaptation time for lamp A varies between 30 to 50 seconds, and for lamp B between 35 to 70 seconds. The dark-adaptation speed for the same

posure time with the highest brightness level. The only exception is in subject E. S. who had steadily increasing thresholds with brightness at the smallest F.C.-seconds values of 200 and 620. The minimum threshold has the tendency to appear at higher brightness levels with increasing F.C.-seconds values including the values of E. S. The results of table 6 indicate that in regard to light adaptation, the length of exposure has a greater effect in raising the threshold at low levels of illumination; whereas at the higher levels of illumination, brightness is the more important factor. In general, the threshold is higher at the highest brightness level than at the longest duration of exposure. In this respect, light adaptation and dark adaptation are different.

threshold varies between 22.5 and 253 seconds for lamp A and between 18 and 235 seconds for lamp B. The seven subjects were selected as manifesting the extremes of slow and of fast dark-adaptation times in a series of 32 subjects,⁷ in order to investigate whether the same subjects show also extreme differences in light-adaptation speed. This is obviously not the case. Table 5 shows similar discrepancies between the three well-trained subjects. The light-adaptation speed of S. S. and E. S. is approximately the same, that of S. B. very much faster. The dark-adaptation speed is fastest in S. B. and slowest in E. S.

In regard to the total dark-adaptation time for equal exposure duration, the values of S. B. are closer to those of E. S.

than to those of S. S. (table 2), since the faster dark-adaptation speed compensates for the faster light-adaptation speed in this subject. This illustrates that measurement alone of dark-adaptation time after standardized exposure cannot reveal the true individual dark-adaptation speed.

The correlation coefficients between light and dark adaptation were calculated

ing dark-adaptation time is compared at two brightness levels for each subject. Only direct readings are given in table 8, so that the threshold values differ slightly, but are still equal within the experimental error. It can be seen that the daily variations of light and of dark adaptation do not coincide. There is a tendency to longer dark adaptation with slower light

TABLE 8

for the 10 subjects at the thresholds of 6 and 9 M.F.C. and 200 F.C. brightness. It was expected that a slower light adaptation would correspond to a faster dark adaptation. The coefficients were $+0.22$ and $+0.2$ for lamp A and $+0.37$ and -0.1 for lamp B. There is no significant correlation between individual light- and individual dark-adaptation speed.

Discrepancies of daily variations of light and dark adaptation. Table 8 shows a few examples of daily variations of light and of dark adaptation in the three well-trained subjects. For each experiment the time to reach a certain threshold value during light exposure and the correspond-

adaptation. This tendency is consistent with our results (table 5) that a longer exposure duration at the same threshold level tends to prolong dark-adaptation time. However, this tendency alone cannot explain the discrepancies in the daily variations of light and dark adaptations in table 8. Discrepancies in the daily variations between light and dark adaptations occurred also in the experiments with the seven less-well-trained subjects.

The effect of spectral distribution on light and dark adaptation. Table 1 shows that the threshold values are lower with lamp B than with lamp A at the higher thresholds, whether they are obtained

with longer exposure times at lower brightness or with shorter exposure times at higher brightness. This is consistent with our former results⁷ of faster dark adaptation with illuminant B after much longer exposure times of two minutes. The superiority of lamp B, however, is not so evident at the shorter exposure times. Obviously, only the secondary slower part of light adaption is clearly influenced by the effect of spectral distribution, while the effect on the initial fast process is doubtful. In the average results from seven subjects light adaptation is slower throughout the whole range of exposure times with lamp B. However, the difference between lamp A and lamp B increases with exposure duration.

In regard to the corresponding duration of dark adaptation (table 2), there is a marked tendency to faster dark adaptation with lamp B at the longer exposure times, the only exception being in subject S. S. at 200 F.C. At the short exposure times of 0.5 and 1 second, most differences between lamp B and lamp A are within the experimental error.

Table 5 may be used to decide whether the faster dark-adaptation time with lamp B can be explained as a consequence of the slower light adaptation with this illuminant, or whether an additional effect on dark adaptation is present. It is plain that a faster light adaptation will produce a longer dark-adaptation *time* even if the actual dark-adaptation *speed* is the same.

Since in table 5 the dark-adaptation time is compared for the same threshold values, the actual dark-adaptation speed is obtained, and the influence of different light-adaptation speed is eliminated. It seems that different individual and brightness trends occur in lamp B and lamp A. The effect of lamp B on light adaptation appears to be more consistent than the effect on dark adaptation.

All seven less-well-trained subjects except Du' had a slower light-adaptation speed with lamp B, either throughout the whole range or at least at the higher M.F.C. thresholds. The effect of lamp B on dark-adaptation speed differed in different subjects. It is interesting to note that individual differences existed in regard to the effect of spectral distribution on light- and on dark-adaptation speed.

COMMENT

Although light-adaptation threshold and corresponding dark-adaptation time increase with brightness and with exposure duration, our results reveal numerous discrepancies between light adaptation and dark adaptation. The increase of dark-adaptation time with increasing exposure duration is not always parallel to the increase of the relative light-adaptation threshold in the same experimental series. Daily variations of light and dark adaptation do not coincide, and there is a lack of correlation between individual dark- and light-adaptation speed. The discrepancy in the daily variations is not surprising, since Hecht¹ observed that the daily variations of the cone and of the rod segment of the dark-adaptation curve may not coincide.

The occurrence of plateaus or of an irregular slope in the increase of relative light-adaptation thresholds and of dark-adaptation time with increasing light-exposure time is probably only an expression of quantitative differences of the same phenomenon. An increase of less than 5 percent of the threshold value in the subsequent exposure duration would still fall into the limit of experimental error. However, the sharp break during the first 0.5 second is best explained with the transition from α to β adaptation.⁹ Schouten and Ornstein⁹ assume that there are at least two different processes of light

adaptation with different parameters. Although a basic photochemical process during light adaptation is certainly present, the pure photochemical relationship between light and dark adaptation is interfered with by several unknown factors. This bears out Hecht's¹ prediction that further suppositions are necessary to describe some visual data. Our results concern cone light and dark adaptation only, and no direct transfer on rod adaptation should be made. However, the whole range of rod adaptation is passed through very rapidly during light exposure even at somewhat dim illumination levels, so that the change of brightness sensitivity occurs in the range of the cones after exposure times as short as 1 second. This does not exclude, of course, that the rod threshold increases simultaneously, although overshadowed by the changes of cone sensitivity. However, it cannot be expected that the relationship between rod dark adaptation and cone light adaptation will be closer than that between cone light and cone dark adaptation.

In a previous paper,⁶ the light penetration through the eyelid was different when calculated for light and dark adaptations, so that we assumed that light adaptation and dark adaptation might be different not only in direction but also in nature. The present results support this conclusion. Dark-adaptation time for a given light threshold increases with the exposure duration necessary to reach this threshold. This is consistent with the observations of Elsberg and Spotnitz¹⁰ on recovery of visibility from glare. Obviously, dark adaptation is involved in this process. Our results confirm Schouten and Ornstein's⁹ finding that different rates of recovery can exist for any sensitivity level and may be regarded as additional evidence for the view¹¹ that a given light threshold cannot be regarded as an equiv-

alent for the concentration of photosensitive material. While increasing exposure duration is a more important factor than increasing brightness for the dark-adaptation time, the effect on light adaptation is different.

There are two practical applications of our results: one is concerned with the technique of dark-adaptation measurements, the other with the appraisal of the glare effect. It can be concluded that the currently used method to standardize conditions for dark-adaptation measurements is not adequate. Usually a standardized light-exposure duration of from one to several minutes is given, after which dark-adaptation time is measured. Due to the lack of correlation between light and dark adaptation speeds, the initial threshold from which dark adaptation starts is different in different subjects. There is some possibility that individual differences will be somewhat levelled at longer exposure durations, but this assumption is neither safe nor supported by the trend of our curves. The present method of measuring dark adaptation is roughly comparable to an attempt to study the oxygen debt after muscular exercise without knowing the work load. There are two ways of measuring the actual dark-adaptation speed: (1) to vary the brightness so that light adaptation speed is comparable; or (2) to vary exposure duration at constant brightness so that the same threshold of light adaptation is attained.

To our knowledge, light and dark adaptations have not yet been used for a comparative study of the glare effect of different illuminants, although both are such fundamental visual processes that they should not be neglected in the appraisal of glare effects. The differences of light and dark adaptation obtained from two different illuminants, A and B, are encouraging for the use of this method. Our

previous results⁷ with dark adaptation alone have been confirmed in this series. The dark-adaptation time is shorter after exposure to lamp B, owing to the changed spectral distribution of this illuminant. In addition, the present series allows a differentiation between the effect on light and on dark adaptation. This is desirable because of the lack of correlation between both processes. Four different combinations of glare effects are possible, which are illustrated by the following scheme, comparing two hypothetical illuminants or conditions x and y.

were used in our previous series, the concordant effect will be still more manifest.

The effect on light adaptation appears to be more important since it concerns the primary response that is responsible for the immediate state of visual sensitivity during light exposure, and also determines to a large extent the recovery time. It may be mentioned that light adaptation can be measured also by indirect methods such as fusion frequency of flicker,¹² brightness-difference thresholds,¹³ or visibility.¹⁴ Since different visual processes

<i>Light Adapt. Speed</i>	<i>Dark Adapt. Speed</i>	<i>Effect</i>
(a) $x = y$	x faster y slower	Same glare effect during exposure; faster dark-adaptation time in x
(b) x faster y slower	$x = y$	Greater glare effect in x during exposure; dark-adaptation time longer in x as a consequence of the faster light adaptation (higher threshold)
(c) x faster y slower	x slower y faster	Concordant: Greater glare effect in x during exposure; dark-adaptation time much longer in x as added effect of faster light-adaptation and slower dark-adaptation speed
(d) x faster y slower	x faster y slower	Discordant: greater glare effect in x is compensated in regard to the dark-adaptation time by the fast dark-adaptation speed

We have evidence for the existence of any one of the combinations (a) to (d) in our experimental material.

Using this scheme for analysis between lamp A and B for a rather wide range of relative light-adaptation thresholds, combination (b) is valid up to 9 M.F.C. This means that the diminished glare effect of lamp B is due to a slower light-adaptation speed without change of dark-adaptation speed. At the longest exposure duration, near 10-M.F.C. threshold, an additional effect on dark adaptation becomes apparent leading to combination (c). This tendency is rather obvious, although not yet quite uniform. Probably, at still longer exposure times, such as

are used as criterion for light adaptation in the indirect methods, no mutual transfer of results is possible.

SUMMARY

1. The effect of brightness levels (between 125 and 1,050 F.C.) and of exposure duration (varied between 0.5 and 100 seconds) on light and on dark cone adaptation was investigated in three well-trained and seven less-well-trained subjects, comparing usual frosted lamps (A) with an illuminant (Verd-A-Ray, lamp B) with reduced radiation at both ends of the visual spectrum.

2. Although dark-adaptation time increases with increasing light-adaptation

threshold, whether due to increasing brightness or exposure duration, there appears to be no consistent relationship between light-adaptation speed and dark-adaptation speed.

3. The dark-adaptation time for a given light-adaptation threshold tends to increase with increasing exposure duration.

4. For the speed of light adaptation the exposure duration appears to be of greater importance than the brightness only at low levels of brightness, whereas with higher illumination the brightness is more important.

5. The increase of the threshold during light adaptation and the increase of dark-adaptation time often do not run parallel.

6. In 10 subjects, no relationship be-

tween individual speed of light and of dark adaptation was noted.

7. Daily variations of light and of dark adaptation do not coincide.

8. The shorter dark-adaptation time of illuminant B, found in previous series, is confirmed. It is, at threshold values up to 9 M.F.C., a result of a slower light adaptation; at longer exposure times and higher threshold values there is an increasing tendency to an additional effect on dark adaptation. This is interpreted as increased tolerance of glare and faster recovery after glare with this illuminant.

9. Implications regarding a standard procedure for exact determination of dark-adaptation speed and analysis of glare effects have been discussed.

THE CONTROL OF EXPERIMENTAL ANTERIOR-CHAMBER INFECTIONS WITH SYSTEMIC PENICILLIN THERAPY*

ARNO E. TOWN, LT. COMDR. (MC), U.S.N.R., FRANCES C. FRISBEE, LT. (JG) H(W), U.S.N.R., AND J. GORDON WISDA, PHM1c, U.S.N.R.

New York

The efficacy of penicillin in the treatment of ocular infections has been extensively studied in animal experimentation as well as by clinical application. Infections of the bulbar and palpebral conjunctivae, ulcerations of the cornea and corneal injuries accompanied by perforation¹⁻⁶ have been successfully treated by local application of penicillin. Gonorrheal ophthalmia in adults^{7,8} has been promptly cured by intramuscular injection of penicillin. The successful response of orbital cellulitis and cavernous-sinus thrombosis^{1,3,5,9,10} to penicillin, parenterally administered, has been reported. One of us (A. E. T.) has treated two patients with severe orbital cellulitis by the systemic administration of penicillin. Clinical improvement was rapid and recovery was uneventful. Scant attention has been given to consideration of the clinical efficacy of this agent in intraocular infections.⁶ Von Sallmann¹¹ found the administration of penicillin by corneal bath and by iontophoresis to be effective in checking experimentally produced pneumococcal infection of the anterior chamber, even when delayed for 12 to 13 hours after inoculation. Treatments were given once or twice daily over a period of two to four days. When there was an associated lens injury, it was found that, to be effective, therapy

must be started earlier and continued over an extended period of time.

In a previous communication, one of us¹² has reported on the concentration of penicillin in the anterior chamber of the rabbit eye following intravenous and intramuscular injection of the drug. The present paper concerns itself with the application of these findings in a study of the effect of intramuscularly administered penicillin in experimental streptococcal infection of the anterior chamber.

EXPERIMENTAL TECHNIQUE

The organism chosen for production of intraocular infection was a penicillin-sensitive strain of nonhemolytic streptococcus. Virulence of the organism had been increased by use of a culture medium containing 5-per cent mucin and by animal passage. The inoculum was a 24-hour culture in brain-heart infusion broth, diluted to one part in 10 or one part in 100 depending on the severity of the initial infection desired.

Rabbits were chosen as the experimental animal. With a fine hypodermic needle, 0.1 ml. of the diluted culture was injected through the upper quadrant of the cornea near the limbus into the anterior chamber. Within 7 to 12 hours a localized area of keratitis could be recognized which progressed rapidly to a generalized keratitis in the untreated animals. A conjunctivitis of varying severity usually manifested itself at the same time.

Penicillin therapy was initiated for each animal at such time as a definite keratitis could be recognized. The dose was approximately 5,000 units per kilo-

gram of body weight, given intramuscularly every three hours.

EXPERIMENTAL FINDINGS

Control animals. Adequate control animals were included in the study to show that the untreated eye, infected by the technique described always went on to extensive generalized keratitis with resultant extensive scarring or complete opacity of the cornea; to an involvement of other parts of the eye; or, in some instances, to a panophthalmia.

Preliminary experiments. A series of preliminary experiments showed the limitations of penicillin to control ocular infection. Their value lies in contrasting the methods used with those in later experiments which were successful. In some of the very early studies, a fulminating infection, recognizable in three or four hours and rapidly progressive, was obtained following the use of excessively heavy inoculum. This difficulty was obviated by further standardization of the virulence of the organism to allow the adoption of a uniform dilution of the culture for successive experiments.

Since it had been previously found that a marked increase in the concentration of penicillin in the aqueous humor of noninfected eyes following paracentesis,¹² one group of animals was treated by intramuscular injection every three hours combined with drainage of the anterior chamber twice daily. By the second day of treatment it became apparent that, in the presence of an infection, the ill effects resulting from puncture of the cornea and withdrawal of aqueous humor, with the consequent disturbance of normal equilibrium within the anterior chamber, was not counterbalanced by the higher concentration of antibacterial agent obtained by this procedure. With continued treatment, the in-

fection became progressively worse and resulted in panophthalmia at the end of three days. Cultures taken on the fifth day were still positive for streptococcus.

In one group of animals, the infection was allowed to progress to a severe keratitis, involving the entire cornea, with massive purulent exudate in the anterior chamber, before treatment was started. Under penicillin therapy the keratitis did not progress further, but so much damage to the cornea had taken place that, from a clinical point of view, the results were discouraging. However, samples of the aqueous humor removed 48 hours after an eight-day course of therapy, were found to be bacteria free. Thus it was shown that anterior-chamber infections may be controlled and eventually eradicated by persistent treatment with penicillin, even when they are so severe and have persisted so long as to cause irreparable damage to the cornea.

Critical experiment. With the aforementioned limitations in mind, a critical experiment was set up with 13 animals. Beginning infection could be recognized in all animals seven hours after injection of the standardized inoculum of streptococcus into the anterior chamber. At that time, one infection was of sufficient severity for initiation of therapy following withdrawal of aqueous for culture. Penicillin injections were started in nine other animals during the next five hours, at such time as a definite keratitis became apparent. It was continued by intramuscular injection of 15,000 units (approximately 5,000 units per kilogram of body weight) every three hours for eight days. The remaining three animals were considered to have insufficient infection for inclusion in the study. It is interesting to note that eight days later one of these was found with pitting cicatrices of the cornea and severe iritis.

TABLE 1

BACTERIOLOGIC FINDINGS ON AQUEOUS HUMOR FROM TEN RABBITS WITH EXPERIMENTAL ANTERIOR-CHAMBER INFECTIONS TREATED WITH PENICILLIN INTRAMUSCULARLY

Rabbit No.	9978	9992	9998	9988	9990	9000	9984	9983	9979	9976
Prior to treatment	Pos.	Pos.	Pos.						Pos.*	
Day of treatment										
2	Pos.	Pos.	Pos.				Pos.		Pos.

8		Neg.	Neg.	Neg.	Neg.	Neg.	Neg.	Neg.		

* Negative after 24 hours, positive after 48 hours incubation.

The bacteriologic findings on samples of aqueous humor withdrawn during the course of therapy are shown in table 1. Due to the previously mentioned altered character of secondary aqueous humor, samples were taken on only 4 of the 10 animals prior to therapy. Cultures were repeated on these four animals on the second day of therapy and, at that time, a fifth animal was added to this group which was to be subjected to frequent bacteriologic study. Samples were not taken from the eyes of the remaining five animals until the infection appeared, from clinical observation, to be under control. Cultures on all 10 treated animals were negative by the eighth day, at which time therapy was discontinued.

The tabulated clinical findings (table 2)

show that, with one exception, the conjunctivitis had disappeared by the fifth day of treatment. Keratitis responded more slowly, but had cleared by the eighth day. There was recurrence in only one animal, brought about, in all probability, by trauma to which the eye was accidentally subjected on the ninth day after initiation of therapy. Hypopyon was present in seven of the infected eyes, appearing with or subsequent to the keratitis. In seven instances an exudate, purulent in nature, occurred in the pupillary area. It was absorbed slowly, assuming a veil-like membranous form, apparently attached to the margin of the iris, before disappearing. In one eye the exudate did not appear until the eleventh day and was thin and membranous when first observed.

TABLE 2

CLINICAL FINDINGS ON TEN RABBITS WITH EXPERIMENTAL ANTERIOR-CHAMBER INFECTIONS TREATED WITH PENICILLIN INTRAMUSCULARLY

Rabbit number	9978	9992	9998	9988	9990	9000	9984	9983	9979	9976

Area of opacity (18th day)	Minute (3)	Small	None	Small	Small	None	Small	None	Minute (3)	Minute

* Conjunctivitis subsided fourth day but recurred on sixth. No recurrence after eighth day.

† Keratitis receded on the eighth day but flared up after accidental trauma on the ninth day, subsiding without recurrence on the eleventh day.

‡ Thin membranous exudate.

Daily examination of the eyes was continued until the eighteenth day, at which time two presented a normal appearance, without evidence of damage. In five instances there was present a small opacity of the cornea in the upper quadrant near the limbus. Two other eyes showed three minute areas of opacity in the same region. The consistent occurrence of opacities at the site where needle punctures were made as well as the fact that multiple areas of opacity were present only in those eyes from which aqueous had been successively withdrawn, points to the fact that they occurred as a result of penetration of the infecting organism into the cellular layers of the cornea along the needle track. In rabbit number 9998 no opacities of the cornea were present on the eighteenth day, but an opacity of the lens was apparent. This eye had responded slowly to treatment, and clouding of the aqueous was observed from the eleventh to the eighteenth day. Apart from damage to the lens, probably resulting from an injury by the needle at one of the punctures, this eye appeared normal.

DISCUSSION

Results obtained in the treatment of infections of the anterior chamber by intramuscular injection of penicillin were in accord with what were to be expected from previous findings in regard to its concentration in the aqueous humor.¹² Because levels of therapeutic activity differ for various infecting organisms, it was suggested that a high dosage level would be required for adequate control of intraocular infection. Actual experimentation showed that a considerably lower dosage was adequate for the streptococcal infection studied.

Injection through the cornea into the anterior chamber of a minute quantity of

an organism which had been standardized at highest virulence by animal passage and the use of mucin broth, resulted in an infection which could be duplicated at will. This technique is a modification of that used by Picot¹³ and, later, by Von Sallmann.¹¹ It entails the use of local anesthesia only and is in contrast to the method used by Robson and Scott² in their work on corneal ulcers. They employed general anesthesia and injected the organisms under the corneal epithelium to produce a bleb in the cornea.

It would appear from accumulated evidence that conjunctivitis, corneal ulcers, and dacryocystitis respond favorably to local treatment with penicillin drops or ointment. In cases of perforating corneal ulcers, perforating injuries to the cornea accompanied by infection, and intraocular infections, the use of this type of local-penicillin therapy has met with considerable disappointment. In 1941, Abraham and his co-workers¹ reported a case of corneal ulcer that showed little improvement after treatment with penicillin drops. When corneal baths were substituted the response was prompt. Von Sallmann¹¹ used the corneal bath as well as iontophoresis, with success in infections of the anterior chamber. He found that this procedure did not result in demonstrable amounts of penicillin in the vitreous humor.¹⁴ In a recent article, Dunnington and Von Sallmann⁶ report success in arresting experimental infection of the deeper portion of the lens and of the vitreous by injection of penicillin directly into the affected part. Such treatment usually failed when an interval of 24 hours was allowed to elapse between the inoculation and therapy. In most instances no permanent damage resulted from the injection of penicillin solution, although a temporary opacity occurred. In the absence of infection, penicillin was injected

into the anterior chamber. This procedure resulted in a moderately inflammatory reaction which persisted for 24 to 72 hours.

These latter findings taken in conjunction with our own experiences that, in the presence of infection, the repeated withdrawal of aqueous was followed by extension of the infection and opacities at site of needle puncture, suggest the need for extreme caution in the use of a therapeutic method which entails puncture of an intact cornea in the presence of an infection. This in no way invalidates the previous observation¹² that an infection accompanying a perforating injury to the eyeball may be expected to respond more readily to systemic penicillin therapy than one in which there is no escape of intra-ocular fluid.

Since the efficacy of local penicillin therapy has been well explored by other

workers, only systemic administration of the antibacterial agent was employed in the experiments reported here. Local application of the drug combined with an intensive regimen of systemic therapy offers promise to the clinician confronted with a serious ocular infection, provided the infecting organism is penicillin-sensitive.

SUMMARY

1. Experimental infections of the anterior chamber of the rabbit eye which could be duplicated at will, were induced.

2. These experimental infections were controlled and, in the absence of lens injury, normal function of the eye was regained following intramuscular administration of penicillin.

3. Massive doses of the drug over an extended period of time were required for successful therapy.

SOCIETY PROCEEDINGS

EDITED BY DONALD J. LYLE

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

February 13, 1945

HYDROPS OF THE CORNEA

DR. RALPH O. RYCHENER reported a case of keratoconus complicated by hydrops of the cornea in a young woman, G. B. W., aged 16 years. On March 6, 1944, she was referred for treatment, showing the typical clinical picture of hydrops of the cornea of the left eye.

Daily paracentesis was performed at the temporal limbus for two weeks. The corneal edema measured 2 to 3 mm. between Bowman's and Descemet's membranes. A 10-percent solution of sodium chloride was used as an eye bath every two hours.

The patient developed hematuria with a hemoglobin of 68 percent and was transferred to Saint Joseph Hospital for urologic treatment. This condition eventually cleared and she was returned home with the cornea still edematous and vision reduced to perception of moving objects. On November 4, 1944, the visual acuity in the right eye was 4/60, improved with a —9.00D. cyl. ax. 60° to 6/60. The visual acuity in the left eye was 6/60, improved with a —2.50D. sph. to 6/12.

The cornea of the right eye showed a marked conical protrusion with deep corneal scarring centrally. The cornea of the left eye showed a nearly normal contour, with corneal scarring to the temporal side of the pupillary area. Apparently, fibrosis following hydrops had compensated for the original keratoconus.

IRIDOCYLITIS FOLLOWING TATTOOING WITH GOLD CHLORIDE

DR. RALPH O. RYCHENER reported a case of tattooing of the cornea for cosmetic improvement which resulted in iridocyclitis and eventual enucleation of the eye. E. H. D., aged 32 years, was seen April 20, 1944. The left eye was divergent from a penetrating injury of the cornea at the age of seven years. There was a linear scar of the cornea at axis 75°, covering the entire pupillary area with anterior synechia below. A traumatic cataract was present. The tension was 40 mm. Hg (Schiøtz). The vision was nil.

The patient was most conscious of the cosmetic appearance of the eye and tattooing of the cornea was done on April 21st, the superficial layers of the scar being excised and 20-percent gold-chloride solution and 20-percent tannic-acid solution applied with an applicator to the eroded area. An excellent golden brown stain of the affected area resulted. However, the eye never became entirely clear and retained a foreign-body feeling which was found to be due to minute sloughing of the impregnated metal. Eventually, it was necessary to remove all of the precipitated gold tannate, but the eye remained irritable, photophobic, and painful, and on October 2, 1944, was enucleated.

SIDEROSIS FOLLOWING INTRALENTICULAR FOREIGN BODY

DR. RALPH O. RYCHENER reported a case of siderosis of the eyeball following a penetrating injury to the cornea and lens. H. R., aged 13 years, was seen for the first time on January 4, 1945, because of failing vision in the left eye for the

previous month. Visual acuity was reduced to moving objects because of a traumatic cataract with iron-pigment deposits on the anterior capsule. A minute penetrating scar was visible in the central cornea, with a corresponding minute hole in the anterior lens capsule, and a dark object approximately 1 mm. in diameter could be seen with the slitlamp in the lower lens cortex. Repeated X-ray pictures were negative for intraocular foreign body. The patient was unaware of any previous injury to the eye but a history was elicited in which he recalled breaking up some iron with a hammer about a year previously. On January 12, 1945, a simple extraction was performed with keratome incision.

The lens capsule could not be grasped for intracapsular extraction but the lens cortex was expelled completely and contained some rust fragments and an oxidized foreign body, 1 mm. in its greatest diameter, which was attracted by close approximation with the giant magnet. Postoperative convalescence had been normal and visual acuity was 6/24 with correction.

X-RAY BURNS COMPLICATED BY GLAUCOMA

DR. E. C. ELLETT presented J. R., aged 55 years, who was seen in December, 1943, with an epithelioma at the lower outer limbus of the left eye. The right eye was normal. The vision of the left eye was 6/60, unimproved with lenses. A growth had been removed from the upper part of the limbus of the left eye, diagnosed grade-3 basal-cell epithelioma, and the operation was followed by X-ray treatment. In January, 1944, the patient had a dermatitis, and there was a faint generalized stain of the cornea of the left eye (fluorescein). He had more X-ray treatment and said he received 5 treatments in

one day and 10 on another day three weeks later. The patient was seen in January, 1945, when there were intense congestion of the eyeball, faint staining of the conjunctiva, and a dense white scar involving the lower and temporal conjunctiva and sclera. It was about 15 mm. in diameter and reached into the fornix. The pain was intense. The pupil was 7 mm. in diameter. The tension was 46 mm. Hg (Schiotz). A retrobulbar injection of novocaine and repeated paracentesis did not control the tension, and an iridectomy was done on February 12th, which reduced the tension. The eye was less red and not painful.

SENILE ECTROPION AND BOWEN'S DISEASE

DR. E. C. ELLETT presented Mr. P., aged 69 years, who had ectropion of both lower lids and a small pterygium on the lower portion of the left eye. From the lower edge of the pterygium a gelatinous substance swept around the cornea below to the temporal side, overriding the cornea about 3 mm. In the discussion of this case, Dr. Rychener and Dr. McKinney called attention to the condition as described by Wescamp of Argentina in the Archives of Ophthalmology (April, 1944).

CORNEAL TRANSPLANTATION FOR KERATOCONUS

DR. J. WESLEY MCKINNEY reported the case of Miss G. H., aged 30 years, who was seen in 1938 for an advanced keratoconus in each eye. The corneal protrusion was so marked in the right eye that a contact glass could not be worn. A molded contact glass, however, was fitted for the left eye. Because of the apical corneal opacity the best vision obtained even with the contact glass was 20/50 partially. In 1941, the cornea of the left eye had be-

come so weakened and the cone so marked that a contact glass could no longer be worn. In 1942, the patient experienced a sudden marked impairment of vision, with pain in the left eye. Examination revealed edema and opacification of the central portion of the cornea involving all the layers. This was a typical hydrops of the cornea resulting from the leakage of aqueous into the cornea through cracks in Descemet's membrane. This cleared up entirely in almost one month with the use of drops of hypertonic sodium chloride. In January, 1944, a corneal transplantation was performed in the left eye. Because of the thinness of the cornea it was very difficult to make as accurate an incision as is usually possible. The graft healed well except for a small area temporally where a fine fistulous tract remained. In July, 1944, this corneal fistula was closed by means of surgical diathermy applied with a very fine needle. Following this procedure the anterior chamber remained flat for about one week. As the anterior chamber re-formed the intraocular pressure rose and was controlled with difficulty with miotics. Consequently, a cyclodialysis was performed. Since this operation the tension has remained normal, and the graft has cleared to almost normal transparency. The vision improved to 20/30 and J4.

DISLOCATION OF LENS INTO ANTERIOR CHAMBER

DR. PHILIP M. LEWIS presented a patient with congenital subluxation of both lenses, one of which became dislocated into the anterior chamber.

E. A., a man, aged 30 years, was seen in September, 1944, for refraction. He was wearing $-5.00D.$ cyl. ax. 90° for both eyes. His vision was R.E. 20/200, L.E. 10/200. Both eyes showed iridodonesis, and the lenses were subluxated

upward and slightly medially. The media were clear and the fundi normal. Refraction showed that vision could be improved to R.E. 20/100 with $-4.00D.$ sph.; L.E. 20/200 with $-5.00D.$ sph. These lenses were prescribed, and he wore them with satisfaction for about two weeks. He then suddenly developed pain in his left eye and vision was blurred. A dense white haze was found in the center of the cornea involving the parenchyma and Descemet's membrane. The lens was in the same position as before. Dionin, atropine, and hot compresses were used, and the patient was examined for possible foci of infection. Some proptitis was discovered and he was treated by his physician. The eye became free from pain, but the cornea still had deep vertical lines of opacities, and the vision was very blurred. He continued at his work, but about once a week he developed a severe pain in the eye which lasted several hours. During that period the vision became very blurred and the eye congested. As these attacks happened to occur each time on a Sunday he was not seen until after the attack was over.

The true nature of these attacks was not discovered until November, when he was seen during one which had not subsided quickly, but on the contrary had lasted over 24 hours. The cornea was very steamy, the intraocular pressure 65 mm. Hg (Schiotz), and the lens was about three fourths in the anterior chamber. Thus the lens was jammed against the posterior corneal surface, and undoubtedly had been doing this to a lesser degree over a period of weeks and had been the cause of the deep corneal clouding. The patient was hospitalized immediately and within an hour the dislocated lens was removed. After healing was complete, the vision was 20/25 with $+13.50D.$ sph. Everything seemed enor-

mous to him and although he saw clearly for the first time in his life, it was very difficult for him to wear the strong plus correction. It was necessary to wear a frosted lens over the right eye to prevent diplopia. After three weeks he had become accustomed to his new glass, the size of objects, and the clear appearance of everything. With his distance lens he could also read J7 at arm's length and could see to do anything he wished except read fine print. A bifocal was not prescribed as it was considered unwise in his case. A separate glass was ordered for reading, +16.00D. sph., with which he read J2.

EARLY MULTIPLE SCLEROSIS

DR. PHILIP M. LEWIS presented R. L., a woman, aged 50 years, with possible early multiple sclerosis.

The patient was seen on December 4, 1944, with the complaint of blurred vision of her right eye for the past two weeks. She stated that she thought she had noticed a slight doubling of images at times. She had noticed no other symptoms and said that she was in good health. Vision was R.E. ability to count fingers, L.E. 20/25. The eyes were normal externally, the media clear, and the fundi normal except for a slight vascular sclerosis. The intraocular pressure was 18 mm. Hg (Schiotz) in each eye. Tests with a red glass and small light in the cardinal directions of gaze failed to reveal any diplopia. The visual fields were fairly normal by confrontation method. It was felt that the condition was probably a retrobulbar neuritis. She was sent to her physician for a complete examination and advised to return for careful studies on the perimeter and tangent screen.

The visual fields of the right eye, taken several times during a two-month period, showed a moderate concentric contrac-

tion. The left peripheral visual field remained normal. Both eyes showed paracentral defects, and the right a very minute central scotoma. The fundi had remained normal, and there had been no other ocular signs of disease. Central vision varied in the right eye from counting fingers to 20/50, although it usually remained about 20/100. In the left eye the vision was 20/25. General physical and laboratory studies were entirely normal. The result of a complete X-ray examination of the skull, sellar region, and paranasal sinuses was normal. The patient was referred to a neurologist with the information that early multiple sclerosis was suspected, but his findings were completely negative. Large doses of thiamine hydrochloride were given without result.

CENTRAL CHOROIDAL DISEASE

DR. PHILIP M. LEWIS presented a patient with a severe involvement of the macular region of unknown etiology. Mrs. W. J. W., aged 49 years, had been seen 10 months previously complaining that for two weeks she was seeing double and the vision of the left eye was blurred. Corrected vision was R.E. 20/20, L.E. 20/100. Examination showed that the right eye was entirely normal. In the left eye the cornea, iris, and lens were normal and the media were clear. The disc was normal and the retinal vessels were only slightly sclerosed. The macula was edematous, and there were several small hemorrhages and two small dull yellowish spots of exudate. Temporally near the equator were several old pigmented areas in the choroid. Complete general physical, dental, and laboratory examinations were negative. She was moderately sensitive to tuberculin.

Injections of tuberculin were given over a period of several months and for a while there was some improvement.

Vision improved to 20/50, and there were no fresh hemorrhages. Recently the condition had become worse. Fresh exudates, edema, and hemorrhages appeared in the macula, which had gradually become considerably scarred. A rather large hemorrhage also occurred along the inferior temporal vein below the macula. Among the various remedies tried in this case were injections of typhoid-H antigen intravenously, and large doses of vitamins. Nothing seemed to be of any value. It was questionable whether this was an inflammatory or degenerative condition.

IRIDOCAPSULOTOMY FOR POSTOPERATIVE MEMBRANES

DR. PHILIP M. LEWIS reported two cases of secondary membrane from postoperative iritis.

Case 1. Mrs. A. R., aged 65 years, had a combined extracapsular cataract extraction in April, 1944. On the second postoperative day the cornea was hazy, the aqueous turbid, and the eye highly inflamed. Treatment consisted of sulfadiazene internally, milk injections, dionin, hot compresses, atropine, and supragenin bitartrate. In spite of all efforts the borders of the coloboma became completely plastered down on a dense membrane. The intraocular pressure rose, and iris bombé developed two months after operation, necessitating transfixion of the iris. Following this, blood filled the anterior chamber and the eye was hard and painful. Paracentesis was performed and the blood evacuated. The eye gradually quieted down, leaving a very dense membrane. About four months after the original operation an iridocapsulotomy was performed, for which a narrow Agnew keratome and Berens modified Noyes scissors were used. Two months later the vision was 20/50 with +11.00D. sph. \approx

+2.00D. cyl. ax. 175° , and with +3.50D. sph. added she could read J6.

Case 2. Mr. T. B., aged 72 years, had a combined extracapsular cataract extraction of the left eye in April, 1944, and three days later a combined intracapsular extraction of the right eye. He went home on the eleventh day with both eyes in good condition, but a little cortex and capsular debris remained in the left eye. However, the fundus was clearly seen and no trouble was anticipated. He was given 1-percent atropine ointment to use in each eye once daily. On the fourteenth postoperative day the left eye became painful. Two days later there was a severe iritis with exudate and blood in the anterior chamber. A paracentesis was performed, with evacuation of the anterior chamber. Foreign-protein injections, dionin, hot compresses, atropine, and supragenin bitartrate were employed. Gradually the inflammation subsided, but the pupillary space was filled with organized exudate. The borders of the coloboma were plastered to the membrane so that iris bombé with increased intraocular pressure developed, necessitating transfixion of the iris.

Four months after the original operation an iridocapsulotomy was performed. Five weeks later the vision was 20/25 with +9.50D. sph. \approx +1.75D. cyl. ax. 180° , and with +3.00D. sph. added he read J2.

Comment. It was felt that dense secondary membranes, especially in cases in which it was necessary to cut the iris, were operated upon more safely and more successfully by keratome incision and snipping with scissors than by ordinary discission with knife needles.

SCIENTIFIC PROGRAM

POSSIBLE ERRORS IN THE USE OF THE
CROSSED CYLINDER

DR. IRVING S. PUNTENNEY discussed certain aspects of Williamson-Noble's recent paper on "A possible fallacy in the use of the crossed cylinder." Part of this work was repeated and photographs were presented which demonstrated that it is easier to make comparisons with the crossed cylinder between a clear image and a blurred image rather than between two images, both blurred but to an equal amount. It was also shown that blurred letters are more easily read when they are elongated in the vertical rather than the horizontal.

The underlying principles of Sturm's conoid as it applies to refraction were also demonstrated by a series of photographs. These photographs were used to illustrate the nature of the two principal planes, the circle of least confusion, size and shape changes of the diffusion circles, and the effect of the crossed cylinder on the size of the diffusion circles in mixed astigmatism. Having shown that size changes in the test letters can be compared but not both size and shape changes, the essayist recommended that the crossed cylinder be used only after establishing meridional balance. The duochrome method seems to be the only known way of consistently establishing meridional balance, and correcting crossed cylinders may also be used as they offer the advantage of both speed and accuracy. The following points were emphasized in the summary:

1. Fogged letters are easier to read when elongated in the vertical.

2. Elongation of test letters can be avoided by establishing meridional balance.

3. When astigmatism is present all refractive errors can be reduced to mixed astigmatism by the addition of plus or minus spheres.

4. Most patients can compare size changes in the test letters, but few if any can accurately determine the difference when both size and shape changes occur.

5. Reducing the distance between the focal lines reduces the size of the circle of least confusion, the smaller diffusion spots being the clearer.

6. The duochrome method seems to be the only known way of consistently establishing meridional balance.

7. Correcting crossed cylinders offer the advantages of both speed and accuracy.

8. The optics of the camera are not directly comparable to the optics of the eye, but studies of this type are valuable for demonstration and teaching.

Discussion. Dr. William A. Mann said that the first true crossed cylinder was devised by Stokes, a mathematician, in 1849. It consisted of equal plus and minus cylindrical lenses so mounted that they could be rotated to any axis desired, and it was suggested that by this means astigmatism could be determined. Little attention appears to have been paid to this idea by refractionists, however, until in 1886 Edward Jackson proposed the use of a crossed cylinder or, rather, spherocylinder, consisting of concave spheres with convex cylinders. The crossed cylinder was at that time advocated for use in determining the strength of the cylinder, and it was not until some 15 years later that it was realized that the axis of the cylinder could also be determined with great accuracy by this method.

Owing to the activity of Jackson,

Crisp, and others, the crossed cylinder has been widely adopted as an aid in subjective tests, and is recognized as one of our most valuable adjuncts in the art and science of refraction. It must be borne in mind, however, that it is a subjective test, and its usefulness is therefore limited by the power of observation and discrimination on the part of the patient. All who use the crossed cylinder routinely have encountered patients who seem unduly unreliable in their replies on this test, and have assumed a lack of discriminatory ability as the basis for their difficulty. This probably remains true, but Dr. Puntenney in his paper has suggested possible reasons for error. By photographic means he has adequately demonstrated the necessity of having the eye under examination meridionally balanced if the crossed cylinder is to be an accurate means of determining the strength of cylindrical correction necessary. Dr. Mann said that he had had no experience with the duochrome test; that it sounds excellent on theoretical grounds, but even without this test it should be quite possible to have the spherical correction exactly balanced, especially when the patient is under a cycloplegic and not subject to the variations in accommodation which may occur in a manifest refraction.

He congratulated Dr. Puntenney upon the photographic demonstration and for emphasizing possible errors which may arise with improper use of the crossed

cylinder. This in no way detracts from the important place of the crossed cylinder in subjective refraction, but does explain the need for its proper use. He asked Dr. Puntenney two questions: (1) Do these same errors arise in determining the axis of the cylinder as in the *strength* (this being the most important use for the crossed cylinder); and (2) in using the duochrome test, how satisfactory a method is it for establishing the meridional correction in a manifest refraction or post-cycloplegic refraction where accommodation may vary?

Dr. Irving Puntenney, in closing, said that regarding the subject of using the crossed cylinder for determining the axis, some work has been done on this, the approach being approximately the same. If meridional balance is maintained throughout the entire test, the axis determination will be more accurate, too, because the errors occur when both size and shape changes are introduced, thus leading to contradictory answers. He said that he had not used the duochrome until about one year ago; that he liked the old-fashioned vision box. However, at Dr. Gifford's suggestion he began to use it. He said he thought Dr. Gifford realized the possibilities of this long ago, and he was inclined to believe that it had helped him more nearly to approach the accuracy of Dr. Gifford's refractions.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to *Dr. Donald J. Lyle*, 904 Carew Tower, Cincinnati 2, Ohio. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 E. Wisconsin Ave., Milwaukee 2, Wisconsin.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THROUGH ENGLISH EYES

The fall sunshine was warm and pleasant, the road to Hot Springs curved gently among the soft Virginian hills, and the dinner menu of The Homestead was in itself a justification for 4,000 miles of travel. To your newest Assistant Editor the November meeting of the American Ophthalmological Society was an unforgettable experience. It was at once a flash-back to far-off days of friendly international meetings and a promise of a saner future. How earnestly we in Eng-

land desire a return to normality can only be realized by those of you who have seen the slow disintegration of prewar life and the gradual exhaustion of a stubborn people under burdens of controls, permits, rationing, universal conscription, and, finally, physical violence. To be snatched from all this to the friendly luxury and exhilarating vitality of America was to be awakened from a painful dream. But the awakening was all too brief, and the return to this land of poverty and post-war fatigue seems the more painful by

contrast. The memory, however, remains and should serve as a basis for a resolution to rebuild, to reconstruct, and to reorganize. One desideratum stands out, true for ophthalmology as for all other types of work, coöperation and collaboration. The Atlantic has narrowed to a span of hours, the continents are no longer individual nor safe in isolation. This should be the basis for an interchange of ideas, of personnel, of teachers, of students, of all that Britain and America have to give each other. This theme might well be developed into a study of the ways and means at present at our disposal. There is much to be done, and the times are urgent. It is good to be at home and planning for peace, not war.

Contrast and Cooperation. It is clear that at the moment the English-speaking world is fatigued but has already begun to realize the inevitable shortage of all medical practitioners, and of specialists. This is especially true of English ophthalmology, and the outstanding difference which a visitor to the United States sees there is in the size of the medical staffs of the teaching eye hospitals. Two examples will make this clear. Hospital A is in the United States. It has 75 beds and an annual out-patient attendance of 22,000. It has a total medical staff of 33, of whom 9 are resident and only 4 are absolute beginners. This makes each person responsible for about 15 cases a week, or, leaving resident staff out of the calculation, the visiting staff need only see at most 18 to 20 cases a week. Hospital B is in England. It has 50 beds and an out-patient attendance of 25,000 a year. Its staff is composed of eight medicals, namely two house surgeons, two surgeons, and four clinical assistants. Here each person must see at least 63 patients a week to keep things going. It is disparities of this nature which we in England must

remedy even before we acquire the modern buildings and equipment we so much need.

Another and interesting difference between the American and British outlook in teaching would appear to be that on one side of the Atlantic the aim is the very thorough and complete training of a relatively few high-grade specialists, while on the other side we aim at basic instruction of a larger number for a shorter time, leaving it to the initiative of the few to obtain for themselves the final gloss and polish of academic distinction requisite for the highest grade. That the ideal lies in a combination of the two attitudes is undoubted, and we may expect the influx of demobilized aspirant ophthalmologists to force the issue of the creation of a new and definite policy. This will on our side certainly aim at coöperation and at fostering travel and interchange of students and staff and at the provision of varying types of instruction, both didactic and practical.

The spirit of reconstruction is abroad, and our respective governments are alive to the need for providing instruction for those whose careers have been interfered with by the war. It is hoped that a plan will emerge in the near future which will do something at least to remedy the serious lack of practitioners of our speciality.

Ida Mann.

THE INTENSIVE COURSE FOR OPHTHALMOLOGIC TRAINING

As everyone knows who takes any interest in the training of ophthalmologists, there is, at the present time, a demand for instruction in the basic subjects and a demand for residencies which is overwhelmingly greater than the existing facilities. Medical schools and hospitals

have been urged to increase their quotas, but the response has not made a dent in the mass of applicants (see the editorial by Cordes in the January number of the Journal).

There has been pressure to relax the requirements for certification by the Boards—indeed, the Advisory Board of Medical Specialties has recommended something of the sort. This the Ophthalmic Board will not do. And yet, something should be done for these eager and ambitious students. Some of them are poor stuff and will bring no credit to ophthalmology. But no doubt some of them will become ophthalmologists of the highest grade. How shortsighted is the policy that is governed by a determination to exclude the poor ones rather than by a resolution to help the good ones! The policy of the American Board of Ophthalmology is the sound one of excluding the poor ones not by refusing to consider any applicant whose opportunities have been poor, but by subjecting him to careful scrutiny in the examinations and passing men whose opportunities may have been poor but who have made such good use of these poor opportunities that they have become so well qualified as to deserve certification. The fact that they have been able to qualify in spite of obstacles is one more evidence of their superior quality.

From time to time, special or emergency problems arise which require special handling. The Board has consistently urged that laboratory and what may be called university methods of instruction are the ideal and that short courses are an abomination—unsound pedagogically and productive of a poor grade of practitioner. They are, however, better than nothing and are capable of really good results under favorable conditions. These favorable conditions are

that the course be comprehensive, systematic, and fundamental—above all, with competent teachers. No one believes that clinical proficiency can be acquired in any way except by handling patients, certainly not by lectures. But for graduate students who have had four to six years of good medical training, including one or more years of internship or private practice or experience in the Armed Forces, the basic subjects of ophthalmology can be taught successfully by lectures, reading, and quizzes. Those who have been practicing ophthalmology will find in such a course a fine opportunity to brush up on their basic knowledge to their great profit.

As secretary of the American Board of Ophthalmology, Dr. S. Judd Beach receives the full impact of the applications as candidates beseech him to tell them what to do, which way to turn. When Ida Mann told him of her success with a lecture course for rather large classes at Oxford, he hoped he had found a solution to the emergency problem of the basic training in fundamental nonclinical subjects preparatory for residencies, many of which make no provision of their own for this training.

There was no time to lose, and already, in less than a month, the organization has been built and is being incorporated. The executive officers are Dr. Beach, Dr. Lancaster, Dr. Terry, Dr. Gundersen, and Lt. Col. Phillips Thygeson. A list of 25 or more advisers has been secured, and a splendid staff of lecturers, assistants, and quiz masters. If the course is the success we hope for, it will be because of the exceptionally competent teachers recruited not only from Boston, but from Maine to California.

We shall see whether it is possible in nine weeks of intensive work to cover the ground thoroughly and adequately.

Walter B. Lancaster.

OPPORTUNITIES FOR TRAINING IN OPHTHALMOLOGY

As of October 1, 1945, the Council on Medical Education and Hospitals of the American Medical Association listed 73 hospitals where otolaryngologic residencies, 56 ophthalmologic residencies, and 43 combined ophthalmologic-otolaryngologic residencies are offered. They are not sufficient, at least in so far as ophthalmology is concerned, to take care of the overwhelming immediate demand, nor very likely to satisfy the demand when the confusion of the present subsides. The long term does not particularly concern us at the moment. The disturbing present requires our attention to see what can be done to alleviate this intolerable condition.

Unquestionably, the stimulating and new Veterans' Administration program for residency training will partly solve this problem for us. It deserves careful scrutiny, and the candidate for ophthalmology should not overlook this opportunity, which may be better in many ways than some of the residencies offered by civilian institutions in so far as clinical material, training, supervised study, and research in ophthalmology are concerned.

At a recent meeting of the Advisory Board for Medical Specialties, Dr. Paul Magnuson, representing the Medical Department of the Veterans' Administration, mentioned that during the next 50 years about 18 million men and women will have been taken care of by the Veterans' Administration hospitals. It is general knowledge that the Veterans' Administration is building and planning to build its hospitals as near to medical centers as possible in order to take advantage of the greatest collection of good doctors. Most of these areas are to be found adjacent to a university and medical school. Mem-

bers of medical faculties of these schools will take active part in helping to staff the hospitals and in assisting in the residency-training program. The clinical material is very great and embraces all age groups. The exservice patients deserve the best of medical care and will get it, if the wise policies of Maj. Gen. Paul R. Hawley, Surgeon General of the Veterans' Administration, are followed. The battle is uphill and difficult, for there are many politicians, professional and amateur, whose philosophy has nothing to do with the ideals of good medical care, and their opposition is a delaying one. Generals Bradley and Hawley deserve every help and great commendation. One has faith that the public, if it knows the facts, will overwhelmingly back up these plans, everywhere.

To be sure, it will take a number of years to complete the building of new veterans' hospitals. However, the old ones are active, and residencies in ophthalmology in them are now available. Reorganizations of the staffs are being carried out, and new attending men and consultants are being appointed. It is good, too, to know that the problems of ophthalmology are in the capable hands of Dr. Trygve Gundersen, formerly consultant in ophthalmology, Mediterranean Theater, and to the Surgeon General of the Army, who has recently been appointed to the post of Chief Consultant in Ophthalmology to the Veterans' Administration. He is charged with the responsibility of organizing the ophthalmic services in the veterans' hospitals. These duties include matters of equipment, choice of consultants, and supervision of the residency-training program for ophthalmologists. It speaks well for the future that this able leader in ophthalmology is at the helm.

The ophthalmologists who are assigned

as attending men to the eye services of these hospitals have great opportunities not only for giving excellent care to the patients but also for developing to a very high degree the teaching facilities of the institution. The best places for the training of residents and internes are those that give the best professional care to the patients.

Let us return for a moment to the matter of the combined eye, ear, nose, and throat residencies mentioned before. A few of these are undoubtedly excellent and offer good facilities for men and women who are planning to do combined work. It is conceded that in small communities, particularly, there is a need for the eye, ear, nose, and throat specialist. There is one advantage at any rate, such an individual is never mistaken for an optometrist by the public. However, the average combined specialist has shown himself in the Army to be poorly equipped for top-flight ophthalmic work, and since these men came from civilian life the findings would be similar for the specialty as a group.

Perhaps some or many of the institutions giving a combined residency can be persuaded, during the emergency shortage of training facilities, at least, to divide their service into two, one for ophthalmology and the other for otolaryngology. This would be profitable to them in that more efficient service could be given, and a valuable boon to the neophyte ophthalmologist seeking a residency, particularly if he had had a basic course beforehand. The probable result would be a raising of the standards of ophthalmic practice among those doing part-time otolaryngology. It would mean a longer term of training for those seeking to be accomplished eye, ear, nose, and throat men; but there is no short cut without the sacrifice of training and skills.

Elsewhere in this issue* will be found an announcement from the American Board of Ophthalmology pertaining to preceptorships. It clearly establishes the policies of the Board in this matter, and puts it up to the student to make a wise choice of a preceptor. It recalls to mind a very attractive phase in the early history of medical education. It would have been a priceless privilege to be chosen pupil on one end of a log with Ernst Fuchs on the other, had he been available. Many a young man in the old days became a fine physician, trotting around with his preceptor on calls and in the office. A good preceptor must be very scarce. He has a reputation as a preceptor to establish and maintain, and if the pupil has to be wise in his choice, the preceptor should be most careful in his, too; for there is something very intimate and very filial in the relationship. One often judges the father by the son, and the son's manners are but a reflection of the old man's influence. A good preceptorship can be like an invaluable heritage, a poor one like a mismatched marriage. It can generate affection, loyalty, and respect or it can produce evil fruits on both sides. A responsive, talented, and eager pupil brings great joy to the preceptor's heart, and in this lies his reward for a difficult task. The future career of his pupil will be followed and supported for the rest of his days. He will know that some measure of immortality at any rate will be his for a time because the preceptor comes to life again at each phrase of his pupil's speech, each turn of his pupil's hand, and each word of an old inherited patient's affectionate memory.

Derrick Vail.

OBITUARY
ALBERT D. FROST
(1889-1945)

Albert D. Frost, known to most of us as "Jack," was killed in an automobile accident near Monterey, Virginia, on his way home from the American Ophthalmological Society meeting in Hot Springs, Virginia, on November 15, 1945.

Born in Pittsburgh, Pennsylvania, on May 20, 1889, he received his preparatory education in the Pittsburgh schools, and in 1912 was graduated from the University of Pittsburgh with the B.S. degree.

He then worked in the steel mills for three years before he decided to enter medical school. Twice he enlisted in the Army and was twice sent back to medical school, and was graduated with the M.D. degree from the Western Pennsylvania Medical College in 1919. Following internship at Bellevue Hospital, Cornell Division, New York City, he spent a year and a half as resident in the New York

Eye, Ear, Nose, and Throat Infirmary. He became associated with the University of Pittsburgh and practiced ophthalmology in his home city until he moved to Columbus in 1924, to become an associate of Dr. Hugh Beatty.

Doctor Frost was a serious thinker. He possessed a keen clinical sense and dexterous hand to execute his plans. He was a resourceful and adroit surgeon. He loved teaching, particularly in the clinic, and his students were thoroughly instructed, in the use of the ophthalmoscope especially, and with contagious enthusiasm. He spared no effort nor convenience to give any student individual instruction merely for the asking. His place as a teacher will be difficult to fill.

"Jack" Frost was extremely friendly, loved to be with groups, and enjoyed, as much as anyone, to lead the chorus of his friends in amiable song.

He was an active member of numerous social, educational, and scientific organizations, contributing scientific discussions to the Columbus Eye, Ear, Nose, and Throat Society, Medical Review Club, Cleveland Ophthalmological Society, Ohio State Medical Association, American Medical Association, and, in particular, to the American Ophthalmological Society, in which he yearly participated. His other memberships included the International College of Surgeons and American Academy of Ophthalmology and Otolaryngology. He ably served for 10 years as a director of the Ohio Commission for the Blind, the last five years as its president.

His fraternal organizations included the Scottish Rite of Free Masonry, Sigma Chi, Phi Rho Sigma, and Alpha Omega Alpha. He was a Son of the American Revolution.

His social and educational memberships included Crichton Club, Young Business Men's Club, Kiwanis, City Club,

Athletic Club, Scioto Country Club, University Club, and Faculty Club.

In recent years he was mainly interested scientifically in the study of papilledema and made several noteworthy contributions on this subject. His published papers were not numerous, but of the highest quality and influence. His death is a real loss to everyone in ophthalmology and is a great loss to his home community, Columbus, Ohio.

A. D. Ruedemann.

CORRESPONDENCE

MEASUREMENT OF ABNORMAL RETINAL CORRESPONDENCE (A SIMPLIFIED METHOD)

Editor,

American Journal of Ophthalmology:

The measurement of abnormal retinal correspondence has often and unnecessarily been made to appear to be an abstruse subject. The idea that such is the case is apt to be fostered by the many articles on the subject in which it is stated or implied that one cannot determine the presence of abnormal correspondence or measure its degree without the use of a major amblyoscope or the afterimage test.

In using the major amblyoscope for this purpose, the examiner has the patient fixate alternately with one eye and with the other and adjusts the targets until they are in such a position that there is no movement of the eye on changing fixation. The patient is then permitted to adjust the instrument until the images of the targets are superimposed or until they change from a crossed position to a homonymous one or vice versa. The difference between this reading and the first one measures the amount of abnormal retinal correspondence. By this procedure there is obtained first an objective, then

a subjective measurement of the angle of squint.

This can be done in the same, or less, time with no other equipment than is used in the examination of any patient with a disturbance of ocular motility. The squint is first measured objectively with the cover test, then subjectively with the Maddox rod, and the degree of abnormal correspondence is the difference between the two findings. The examination with the Maddox rod is facilitated by placing the rod before one eye and a red glass before the other; also by darkening the room somewhat.

The examination as just described can be made, of course, only in patients whose visual acuity in the poorer eye is sufficient to permit central fixation. If central fixation cannot be held, the objective measurement must be made with one of the less accurate methods (perimeter, Priestley Smith tape).

HOW CAN THE OPHTHALMOLOGIST DIVIDE THE BURDEN OF HIS PRACTICE BETWEEN HIMSELF AND HIS OFFICE HELP?

Editor,

American Journal of Ophthalmology:

If a patient is going to consult an ophthalmologist or, as a matter of fact, any physician, he expects and has the right to expect to be examined and treated by the doctor of his choice. Most doctors are very busy men (or women); their working hours are filled to capacity, and it seems only natural that they try to distribute the work to a certain extent between themselves and their nonmedical help. The question comes up, how far this division can be carried without doing

injustice to the patient, on the one hand, and harm to the medical profession, on the other.

Primarily, the duties of a doctor's secretary are well defined. She is expected to operate the telephone, to receive and register the patients in the reception room, to take care of the technical part of the doctor's practice, keep the patient's records and files straight and up to date, send out the statements at regular intervals as directed by her employer, watch all sorts of supplies and order replenishments if something is running low, and assist the doctor in the minor operations which he performs in his office.

In case the doctor has hired a trained nurse or a technician in addition to the secretary the orbit of activities of such personnel naturally will be considerably wider. A trained nurse may give subcutaneous or intramuscular injections under the doctor's strict supervision and responsibility. A technician may relieve him of most of his necessary laboratory work. If properly qualified, a technician may conduct orthoptic treatment of patients.

However, there are certain diagnostic and therapeutic duties which belong strictly in the realm of the doctor and should be carried out by him. The first and extremely important part of the whole procedure is the taking of case histories, which requires not only a great deal of technical, psychologic, and medical experience but also establishes the cherished, inviolate, and much-spoken-of patient-doctor relationship (which, by the way, has nothing to do with fees or with any other material compensation). The nurse may establish a few facts; such as, for example, when the patient got his last glasses, if any, and by whom he was referred. It is, however, the understanding questioning by the doctor and the understanding interpretation of the patient's

answers that build up a useful case history which alone furnishes the working basis for subsequent diagnosis and therapy.

It is not the purpose of this communication to discuss such duties as far as general practitioners and specialists in other fields are concerned. In what follows only the activities of ophthalmologists and their office staffs will be discussed. In my opinion all essential examinations should be carried out by the ophthalmologist—not by office girls or nurses—and these include not only ophthalmoscopy, retinoscopy, slitlamp examinations, but also subjective refraction, tonometry, and campimetry, to name only a few common diagnostic procedures.

I am very well aware of the fact that a certain number of eminent and nationally known ophthalmologists prefer to let an office girl or a nurse take care of some of these diagnostic procedures, especially tonometry and campimetry, the latter being a tedious and time-consuming undertaking if properly performed, which means that not only a peripheral field for gray objects, but also color fields, central field, enlargement of the blind spot, and possible scotoma are included in the examination. Every experienced ophthalmologist knows well what a vast amount of training and knowledge of physiology and anatomy, neurology, clinical pathology, and other branches of medicine are necessary to master the art of campimetry so thoroughly as to make the contribution of campimetry to the establishment of a proper diagnosis worthwhile.

To relate one of many rather typical experiences: A man, aged 30 years, was accompanied to my office by his wife. When he entered the examination room his somewhat ataxic gait immediately aroused suspicion. Questioning revealed that the patient had suffered a "nervous breakdown" four years ago, which meant

that he had shown a great variety of central nervous system symptoms, had been psychoanalyzed, had had his teeth pulled, his tonsils removed, and had had several pairs of glasses prescribed by an ophthalmologist; that he was sometimes better, sometimes worse. Eye examination revealed nystagmus in end positions, convergence paresis, definite pallor of the temporal sectors of both optic discs, deterioration of vision, and central scotoma for all values. When I telephoned the internist who had been taking care of the patient he hurried over to my office very much excited and depressed, bringing along several visual fields, old and recent ones, taken by the office girl in another ophthalmologist's office, which all showed normal peripheral limits. Based mostly upon the judgment of the ophthalmologist and upon the "normal" visual fields the diagnosis of malingering with an outspoken aversion to labor had been made, and the poor fellow had been treated accordingly for years. He died 11 months later from his multiple sclerosis. Had the ophthalmologist taken the trouble to examine the patient's eyes personally and properly the easy diagnosis would never have been missed.

There are in this country ophthalmologist's offices where admittedly the bulk of the refractive work is done by office girls who are only rather superficially acquainted with the fundamentals of refraction. I personally heard one eminent mid-western ophthalmologist, a medical school professor, at a special-guest lecture on the subject of glaucoma frankly advocate leaving tonometry in such cases up to nurses.

What applies to diagnostic measures is also true concerning therapy. I know offices of certificated ophthalmologists in which office girls without any medical training take charge the moment the doc-

tor is leaving town, not only for a day or two, but for weeks, giving typhoid shots, removing corneal foreign bodies, treating critical cases of glaucoma, corneal ulcers, and other serious lesions. Well, some doctors apparently think that such procedures are not only legitimate but also proper. The office girls have worked for them and with them for several years and have seen so many cases of this and that that they are well capable (in the doctor's opinion) to take care of the doctor's practice while he is away. Of course, it is quite possible that a fairly intelligent girl with high-school or even junior-college education can learn a number of clinical procedures. She may learn to irrigate and probe a tear duct, open abscesses, curette chalazions. Such knowledge and dexterity undoubtedly can be acquired by laymen.

However, there is one very serious implication. We, as members of the medical profession, are always watching for infringements by various groups of lay practitioners; that is, those who do not hold an M.D. degree and are not licensed to practice medicine. We are very much opposed to any transgression of limits by them. Optometrists are not permitted to use cycloplegics, anesthetics, nor any other drug. Reputable firms engaged in the manufacture of contact lenses are required to engage the services of an ophthalmologist who has nothing to do but put a drop of an anesthetic in the eyes in order to enable the technician to make the cast.

I do not advocate that technicians and optometrists be free to use all sorts of drugs in patients' eyes; on the other hand, I am strongly against the increasing habit of permitting office girls, technicians, and nurses to do any kind of diagnostic and therapeutic work which should be carried out by the ophthalmologist himself. Certain sudden emergencies

such as drowning, road accidents, and the like always call for the immediate help of laymen where the physician is not at once available. During this war a U.S.N. pharmacist mate at sea on a submarine successfully performed an appendectomy, using for the most part kitchen utensils. Babies have been delivered by young medics in occupied territories who had no previous experience nor knowledge of obstetrics. An attentive intelligent nurse who has seen a large number of iridectomies might be able not only to diagnose an acute glaucoma attack but even to perform the iridectomy. And that might be permissible in an isolated jungle outpost without medical officer. But it certainly is strictly contraindicated under regular civilian conditions. We may start in training a girl in refractive work, in taking visual fields, in tonometry, but where do we end? The next step would be ophthalmoscopy, then minor surgery, and finally the doctor may just perform the more expensive cataract, glaucoma, and retinal-detachment operations, leaving the rest of the diagnostic and therapeutic office activities to a nonmedical staff. That may sound fantastic but it isn't. I could enumerate many amazing examples of that sort.

If we do not take a firm stand, we are not only degrading the reputation of our profession, but we also are deliberately furnishing formidable weapons to all the various groups of nonmedical practitioners who always claim that they are at least as good if not better than the Doctor of Medicine. They will seize any occasion to point to the fact that our diagnostic and therapeutic methods do not have to be acquired in grade-A medical schools; since they can be easily acquired and used by untrained lay personnel who never went through a regular course of training in Medicine nor had

any postgraduate specialized training.

If doctors tell us that they do not have the time to perform personally all necessary diagnostic and therapeutic procedures, it can only be answered that no doctor can be forced to take more patients than he is able to handle, but that every doctor is compelled to diagnose and treat all his patients with the utmost care and that he must avoid everything that could be construed as unethical or detrimental to health-seeking humanity.

Especially now, when strong groups are working for introduction of systems of government-controlled medicine, it is of the utmost importance that the medical profession shall be in a position and eager to prove that we are really giving appropriate care to the whole population, that we are willing and able to take care of our own professional affairs without governmental interference.

Just as the specialists in all fields have established examining boards to which qualified specialists submit evidence of a minimum training, so it may become advisable to establish certain standards defining the duties of professional men in carrying on their practice. It will be better for the profession to take such matters in their own hands than to have them regulated later by governmental decree.

MILITARY OPHTHALMOLOGIC MEETING
HELD AT CRILE GENERAL HOSPITAL,
CLEVELAND, OHIO, NOVEMBER
28-30, 1945

A military ophthalmologic meeting was held at Crile General Hospital, Cleveland, Ohio, on November 28 to 30, 1945. Those present were ophthalmologists in the

Army and Air Force installations who have been vitally concerned with ophthalmologic problems; those who have made noteworthy contributions while in the Armed Forces, although they may now be inactive or on terminal leave; and civilian consultants who have contributed to surgery concerning military ophthalmology.

Following a short speech of welcome by Col. G. V. Emerson, Commanding Officer of Crile General Hospital, and Lt. Col. N. D. Hall, Chief of the Surgical Service of that Hospital, the meeting was called to order at 9:00 A.M.

The first day's program consisted of a symposium on "Orbital reconstruction."

The morning of the second day's program began with a presentation by Lt. Col. M. E. Randolph, Eye Consultant, Surgeon General's Office, Washington, D.C., and Chief of the Department of Ophthalmology and the Rehabilitation Center for the Blind at Valley Forge General Hospital. His topic was "Rehabilitation of the blind." The remainder of the morning's program was devoted to other special topics and original ophthalmologic contributions by various members present.

The afternoon of the second day was in charge of Lt. Col. P. R. McDonald, Executive, Medical Service Branch, Air Surgeon's Office, Professional Division, Washington, D.C. The papers for this session were presented by the outstanding ophthalmologists from the Army Air Force Medical Centers.

A dinner was held at the Cleveland Athletic Club on the evening of the second day.

The morning of the third day was devoted to a symposium on "Plastic surgery of the eyelids." The afternoon session consisted of papers, demonstrations, and discussions concerning localization and

removal of intraocular foreign bodies. All papers were limited to 20 minutes so that ample time for discussion was available.

The 41 ophthalmologists from various parts of the country who attended felt that the meeting was extremely worthwhile, and many expressed the hope that similar meetings in the different eye surgical centers could be held annually.

Chief, Eye Surgical Center,
Crile General Hospital,
Cleveland 9, Ohio

PROGRAM

Wednesday morning, November 28, 1945. 8:30 Registration. 9:00: Col. G. V. Emerson, Commanding Officer, Crile General Hospital, and Lt. Col. N. D. Hall, Chief, Surgical Service, Crile General Hospital, "Welcome." SYMPOSIUM ON ORBITAL RECONSTRUCTION. 9:30: Lt. Col. Gilbert C. Struble, Chief, Eye Surgical Center, Crile General Hospital; "The use of tantalum and the Ruedemann eye implant in orbital reconstruction with presentation of cases;" 9:50: Discussion; 10:00: Lt. Col. E. L. Shiffet, Chief, Department of Radiology, Crile General Hospital, "The use of orbital tracings as an aid in reconstructive surgery of the orbit;" 10:20: Discussion; 10:30: Dr. A. D. Ruedemann, Chief, Department of Ophthalmology, Cleveland Clinic Hospital and Civilian Eye Consultant, Crile General Hospital, "Discussion on the use of tantalum and the implant eye in orbital reconstruction;" 10:50: Motion pictures of operative technique; 11:00: Capt. James Clifford, D.C., Chief, Acrylic Eye Laboratory, Crile General Hospital, "The processing of the Ruedemann implant eye;" 11:20: Discussion; 12:00: Luncheon at Officers' Mess, Crile General Hospital.

Wednesday afternoon, SYMPOSIUM ON ORBITAL RECONSTRUCTION. 1:00: Lt. Col. N. L. Cutler, Dibble General Hospital; "A new orbital implant;" 1:20: Discussion; 1:30: Major G. L. Witter, Dibble General Hospital; "The use of fascia lata in retro-tarsal atrophy following enucleation;" 1:50: Discussion; 2:00: Major A. J. Kreft, M.C., Billings General Hospital, "Orbital and ocular injuries produced by modern war missiles;" 2:20: Discussion; 2:30: Intermission; 2:40: Capt. B. F. Souders, Dibble General Hospital, "Elevation of orbital contents with plastic plates;" 3:00: Discussion; 3:10: Major G. L. Witter, Dibble General Hospital, "The use of dermal instead of fat implants in deep sockets;" 3:30: Discussion; 3:40: Major Victor H. Deitz, D.C., Chief, Plastic Eye Service, Halloran General Hospital, "The evaluation of recent ophthalmic concepts as related to the fabrication of plastic artificial eyes and implant devices;" 4:00: Discussion.

Thursday morning, November 29, 1945. 8:30: Lt. Col. M. E. Randolph, Eye Consultant, Surgeon General's Office, Washington, D.C., and Chief of the Department of Ophthalmology, Valley Forge General Hospital, "Rehabilitation of the blind;" 8:50: Discussion; 9:00: Major Trygve Gundersen, Eye Consultant, Surgeon General's Office, "The Vossious ring phenomenon;" 9:20: Discussion; 9:30: Major H. G. Scheie, Crile General Hospital, "Ocular changes in scrub typhus;" 9:50: Discussion; 10:00: Intermission; 10:10:

Lt. Col. O. W. Thoeny, Beaumont General Hospital, "Malignant tumor of choroid simulating cyst of optic disc;" 10:30: Discussion; 10:40: Major L. J. Croll, Fletcher General Hospital, "End results in the treatment of retinal detachments at Crile General Hospital;" 11:00: Discussion; 11:10: Capt. John S. McGavie, Valley Forge General Hospital, "Visual disturbances associated with head injuries or the treatment of uveitis with artificial fever;" 11:30: Discussion; 12:00: Luncheon in Officers' Mess.

Thursday afternoon, AAF PROGRAM. 1:00: Lt. Col. P. R. McDonald, Executive, Medical Service Branch, Air Surgeon's Office, Professional Division, Washington, D.C., "Testing of night vision;" 1:20: Discussion; 1:30: Lt. Col. Brittain F. Payne, Randolph Field, Texas, "Recent ophthalmic problems in the Philippine Islands;" 1:50: Discussion; 2:00: Major J. H. Allen, University Hospital, Iowa City, Iowa, "Dendritic keratitis;" 2:20: Discussion; 2:30: Intermission; 2:40: Capt. Richard G. Scobee, St. Louis, Missouri, "Ocular muscle balance in flying personnel;" 3:00: Discussion; 3:10: Lt. Col. Phillips Thygeson, AAF, Tampa, Florida, "Blepharitis in military personnel;" 3:30: Discussion; 3:40: Major S. Rodman Irvine, AAF Regional Hospital, Tampa, Florida, "Physiology of ocular movements;" 4:00: Discussion; 4:10: Lt. Col. John L. Matthews, AAF, Randolph Field, Texas, Open; 4:30: Discussion; 4:40: Major D. L. Edwards, AAF, Miami, Florida, Open.

Thursday evening, 7:00: Informal dinner; Cleveland Athletic Club.

Friday morning, November 30, 1945, SYMPOSIUM ON PLASTIC SURGERY OF THE EYELIDS. 8:30: Lt. Col. N. L. Cutler, Dibble General Hospital, "Correction of large notching defect of upper lid;" 8:50: Discussion; 9:00: Lt. Col. S. A. Fox, Newton D. Baker General Hospital, "Repair of lid margin deformities;" 9:20: Discussion; 9:30: Capt. A. E. Sherman, O'Reilly General Hospital, "Choice of procedure in ophthalmic-plastic surgery;"

"Free skin grafts vs. pedicle grafts;" "Repair of notch and colobomatous defects;" "Surgery of the lateral and medial canthus;" "Reconstruction of the entire eyelid;" "Correction of deformities of the eye socket;" "Eyebrow and eyelash grafts;" "Filling of defects of the orbital margin;" 9:50: Discussion; 10:00: Intermission; 10:10: Lt. Col. N. L. Cutler, Dibble General Hospital, "Transplantation of vitreous;" 10:30: Discussion; 10:40: Lt. Col. O. W. Thoeny, Beaumont General Hospital, "A method of surgical treatment of recurrent pterygium;" 11:00: Discussion; 11:10: Major George A. Filmer, Beaumont General Hospital, "An alternate method of eyelash transplant;" "Treatment of relaxed eyelids following enucleation;" "A case of myositis of the ocular muscles;" 11:30: Discussion; 12:00: Luncheon in Officers' Mess.

Friday afternoon, SYMPOSIUM ON INTRAOCULAR FOREIGN BODIES. 1:00: Lt. Col. Riwehun, Walter Reed General Hospital, "Removal of intra-ocular foreign bodies (magnetic and repair of detached retina);" 1:30: Discussion; 1:40: Major H. G. Scheie, Crile General Hospital, "Oxygen injection of Tenon's capsule as an aid in localization of intraocular metallic foreign bodies;" 2:00: Discussion; 2:10: Major Albert Abbott, Valley Forge General Hospital, "The use of the Berman locator in the removal of intraocular metallic foreign bodies;" 2:30: Discussion; 2:40: Lt. Col. Gilbert C. Struble, Chief, Eye Surgical Center, Crile General Hospital, "Technical refinements in the removal of magnetic intraocular foreign bodies from the posterior segment of the eye;" 3:00: Discussion; 3:10: Intermission; 3:20: Dr. A. D. Ruedemann, Cleveland Clinic Hospital, Cleveland, Ohio, "The role of beta radium in the treatment of pathology of the anterior segment of the eye;" 3:40: Discussion; 3:50: Lt. Col. Edward E. Burch, O'Reilly General Hospital, "Administrative problems and procedures in military ophthalmology;" 4:10: Discussion.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the *Ophthalmic Year Book*. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the *Journal*.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

RETINA AND VITREOUS

Bettman, J. W. **Allergic retinosis.** *Amer. Jour. Ophth.*, 1945, v. 28, Dec. pp. 1323-1328.

Damel, C. S., and Brodsky, M. **Arteriolar thrombosis of the retina.** *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Sept., p. 429.

A man, 33 years of age, presented a thrombosis of a small arteriole in the macular region of the right eye, with moderate visual reduction. The neighboring arterioles showed discrete arteriosclerotic changes, but the rest of the retinal vessels were essentially normal. The patient was a chronic alcoholic and several days prior to the examination became unconscious and remained so for six hours. After considering embolism, endarteritis, periarteritis, and thromboangiitis obliterans, the authors arrive at the diagnosis of retinal arteriolar thrombosis, a nosological entity well established by Friedenwald. The pathology of the condition

is briefly reviewed. (5 illustrations, 3 tables, bibliography.)

Plinio Montalván.

Dellaporta, N. **Spontaneous recovery from a retinal rupture after shotgun injury.** *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 363.

A man, 48 years of age, was accidentally hit in the right eye by a pellet from a shotgun. It was assumed that the pellet had pierced the sclera and lodged in the interior of the eye, although roentgenograms were not available. The fundus showed a grayish-white pear-shaped mass protruding from the retina. Adjacent to that spot a small diffuse retinal hemorrhage was found. An attempt to find the pellet through an incision in the lower part of the bulbar conjunctiva was unsuccessful. Three weeks later the gray mass had disappeared and a V-shaped tear in the retina with cloudy curled edges was found. Vision was 6/9 and the field of vision normal. The hole in the retina gradually became smaller

and disappeared completely after two months without any treatment. (References.)

F. Nelson.

Elwyn, H. Diabetic retinitis. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 187-190.

Diabetic retinitis, or retinopathy, is an easily recognizable ophthalmoscopic entity characterized by small, round and irregular hemorrhages; sharply defined, white exudates in the deeper layers of the retina, due to hyalin and lipids; and yellowish-white, glistening exudates, due to deposits of cholesterol.

The ophthalmoscopic picture is at times complicated by changes in the retinal vessels and their consequences, such as aging, arteriosclerosis, contraction of small vessels, obstruction of a venous branch, and episodal arteriospastic retinopathy. There is no causal relation between these changes and those of diabetic retinitis.

Some of the cases of severe diabetic retinitis are characterized by large retinal hemorrhages which rupture into the vitreous. A few cases are also characterized by the proliferation in the retina and the vitreous of newly formed vessels, which are covered by a connective-tissue layer. This form of retinitis proliferans differs in its appearance and its genesis from the retinitis proliferans following the partial absorption of a hemorrhage in the vitreous.

It is his opinion that in its pathogenesis diabetic retinitis stands in close relation to the continuous hyperglycemia which is in all probability responsible for the condition in the capillaries resulting in hemorrhages.

R. W. Danielson.

Franceschetti, M. A. Complete nonsyphilitic sclerosis of the retinal vessels. *Bull. Soc. d'Opht. de Paris*, 1939, Oct.-Dec., pp. 606-607.

A case of sclerosis of the retinal vessels in a man 49 years of age is discussed. He had had diminished vision in one eye since the age of six years, but severe eye symptoms did not develop until 25 years later. Then optic-nerve atrophy developed bilaterally with divergent strabismus, rotatory nystagmus, and complete sclerosis of the arteries and veins of the retina. The Wassermann reactions of the blood and cerebrospinal fluid were both negative. Cranial trauma might have produced this condition. It could also be a manifestation of atypical tapetoretinal degeneration without consanguinity of the parents. Morton R. Cholst.

Magitot, A. Mechanism of the stellate retinopathies. *Ann. d'Ocul.*, 1941, v. 177, no. 11, pp. 395-414.

The many conditions which produce stellate retinopathies are basically due to circulatory disturbances with mechanical and chemical variants. These are hydromechanical pressure of venous and arterial blood, osmotic pressure, the composition of the blood, and the presence of toxic products. Cellular degeneration is brought about by the accumulation of toxic products in the fluids which bathe the retinal cells, especially in the inner layers. Anoxemia and other insufficiencies play an important part because of high retinal glycolysis. The macula is predominantly involved because of the radial arrangement of its vascular structure and nerve fibers. White exudates are largely due to fibrin deposits and the accumulation of granular detritus in macrophagocytic microglial cells. The cells, which frequently form large clumps, are crammed full of lipoids, and giant cells are common in clumps. Vascular lesions can almost always be found, par-

ticularly in the smaller arterioles and the vessels. Hemorrhages are due to transudation, and not to rupture of the vessel walls.

Chas. A. Bahn.

Moeschlin-Sandoz, Y. **Histologic structure of the vitreous ring.** *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 310.

Vogt's vitreous ring is seen frequently in senile eyes and in axial myopia. Histologic studies of the structure of the ring formation have never been published. The author reports his histologic studies of three eyeballs which had shown prepapillary ring formation clinically. One eye was enucleated because of malignant melanoma of the choroid, the two others belonged to a 73-year-old male who died of an intestinal carcinoma. All three eyes showed identical histologic findings. There was spindle shaped splitting of the posterior hyaloid membrane with invasion of cells having the form, structure, and tinctorial characteristics of glia cells, which proves that the strand composing the ring formation as seen ophthalmoscopically is glial in nature. (9 microphotographs, 1 color plate with 3 figures, bibliography.) F. Nelson.

Reese, A. B., and Payne, F. **Persistence of primary vitreous.** *Amer. Jour. Ophth.*, 1946, v. 29, Jan., pp. 1-24.

Terry, T. L. **Ocular maldevelopment.** *Jour. Amer. Med. Assoc.*, 1945, v. 127, June 23, p. 582.

Over 10 percent of infants born very prematurely or weighing three pounds or less can be expected to be blind from retrolental fibroplasia. A large mass of fibrous tissue develops in the hyaloid system. In addition to the mass one finds microphthalmia, shallow or absent anterior chamber, fetal blue iris,

thin ciliary processes, persistent hyaloid artery, retinal separation, searching nystagmus, and photophobia. Of the probable causes listed, premature exposure to light is considered most probable and should be avoided. Treatment has been unsatisfactory. Many such eyes have been removed because the lesion was mistaken for retinoblastoma.

Morris Kaplan.

Vancea, P., and Lazarescu. **Retinal folds caused by pressure from a mucocele of the frontal sinus invading the orbit.** *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 354.

The authors report a case of a large mucocele in a male 54 years of age which after two years duration had invaded the orbit, causing ptosis of the upper lid, proptosis and dislocation of the eyeball downward and outward, as well as restriction of the eye movements. Vision was reduced to 1/50. There was papilledema and retinal hemorrhage, and 10-12 horizontal and parallel folds of the retina were seen running across the macular region towards the disc. After surgical removal of the mucocele the eye returned to its normal position, and after ten days the retinal folds began to disappear. A hyperopic astigmatism found to be 2.5D. before the operation decreased to 2.0D. It is probable that the retinal folds as well as the increased corneal astigmatism were produced by direct pressure exerted by the mucocele on the eyeball. (1 fundus picture, bibliography.) F. Nelson.

OPTIC NERVE AND TOXIC AMBLYOPIAS

Cooper, Fred. **Early diagnosis and treatment of primary optic atrophy.**

The Eye, Ear, Nose, and Throat Monthly, 1944, v. 23, Feb., pp. 68-71.

It is estimated that one tenth of our population is infected with lues and that five percent of the syphilitics develop tabes. It is believed that there are 50,000 cases of primary optic atrophy which are due to acquired lues. Prevention becomes an important problem, and to this end an early diagnosis and immediate treatment seem essential, although opinions differ on this point. The routine ophthalmologic procedures needed to establish a diagnosis are described in detail. The etiologic factors other than lues are enumerated as well as the theories concerning its pathogenesis. He mentions the possible relationship between neurologic changes and vitamin deficiency, and the theory that optic atrophy may develop as a result of nutritional disturbances of the nerve due to a luetic involvement of the blood supply of the optic nerve. The writer discusses different types of local and general treatment and points out that in unilateral luetic optic atrophy an early diagnosis and immediate treatment will in most cases prevent blindness in the fellow eye. Hyperpyrexia induced by malaria is a very efficacious method in the treatment of primary optic atrophy, and tryparsamide is contraindicated in cases where there is actual or potential damage to the optic nerve. (References.)

M. Lombardo.

Halbertsma, K. T. Arteriosclerotic atrophy of the optic nerve. *Ophthalmologica*, 1942, v. 104, Dec., pp. 289-300.

A case of bilateral arteriosclerotic optic atrophy in a woman 53 years of age is reported. The author discusses the theories concerning the mechanism of this type of atrophy. While some

authors hold that the nerve damage is due to inflammation and stasis, the writer emphasizes the effect of pressure by arteriosclerotic vessels. The internal carotid and ophthalmic arteries as well as the vessels surrounding the optic nerve can damage the nerve.

Max Hirschfelder.

Lijó Pavia, J. Prepapillary cyst. *Rev. Oto-Neuro-Oft.*, 1944, v. 19, Oct., pp. 125-131.

The author feels, as do other American observers, that these cysts originate from Cloquet's canal, and dilate as they develop. Two cases of typical prepapillary cyst are reported, both occurring in adults, one in each sex. They were best observed with the binocular ophthalmoscope, which readily demonstrated their anterior protrusion into the vitreous. Both patients had reduced vision, due probably to trophically unhealthy retinas resulting from partial closure of the arteries. Visual-field studies showed enlargement of the blind spot. The author reemphasizes the value of binocular ophthalmoscopy for proper diagnosis and study. (4 retinographs, bibliography.)

Edward Saskin.

Loewenstein, A. Cavernous degeneration, necrosis and other regressive processes in optic nerve with vascular disease of eye. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 220-226.

Several explanations of cavernous degeneration in the nerve have been advanced. The first is that the condition is the result of increased intraocular pressure; another that an abnormal lytic process is at work, the result of lysins which are liberated in the intraocular fluid of glaucomatous eyes (Elschnig). The author's findings lead

him to think that these two views are untenable, for cavernous change is not limited to the prelaminar and the immediately postlaminar part of the nerve. Usually the changes to be described are situated at some distance from the lamina cribrosa as well as near it. It has also been suggested that cavernous degeneration is the result of ascending degeneration in the nerve, a sequel of destruction of fibers at the disc associated with glaucoma, but in this case the cavernous change should present a continuity of degeneration, and its intensity should be greatest near the disc.

Loewenstein stresses that cavernous degeneration in the nerve is but one of the pathologic changes he has found in his study. The others were necrotic and sclerotic alterations.

This paper is a report of the histologic study of six glaucomatous eyes. Two points engaged the attention of the author as the result of the study of these six cases. The first is the occurrence of subretinal prolapse of optic-nerve tissue as a result of disease processes in the nerve. The second, and major, point of interest is the variety of forms of degeneration appearing consistently in the nerve in association with profound vascular disease.

Special attention, in the study, was given to the pathologic types of degeneration in the optic nerves, and the observations are described in some detail. Cavernous and necrotic degeneration were almost consistently found, and frequently the two changes occurred together. They were sometimes present in marked degree; at others they were inconspicuous. In some cases the disease process exceeded the boundaries of the nerve head and extended into the subretinal space.

These observations led Loewenstein to conclude that all these degenerative changes are the result of vascular damage with impairment of nutrition rather than the effect of increased intraocular pressure. R. W. Danielson.

EYEBALL AND ORBIT

Offret, G. Anatomic study of a complex retrobulbar embryonic malformation. *Arch. d'Ophth.*, 1945, v. 5, no. 1, p. 8.

The autopsy specimen studied came from the orbit of a newborn baby and was unique because of the presence of embryonic lid elements lying posterior to the globe. This poorly developed lid structure included such elements as skin, mucous membrane, hair follicles, and sebaceous, sweat, and mucous glands, as well as lobules corresponding to a rudimentary lacrimal gland. In addition there were a number of cysts, some probably representing dilated excretory ducts and others epithelial inclusion cysts. The author differentiates this formation from the ordinary dermoid cyst, which it resembles in many respects, on the basis of the multiplicity of the cystic cavities, the variety of the glandular structures, the resemblance to an eyelid, and the location in the muscle cone which is an unlikely one for a dermoid. He places the tumor intermediate between a dermoid cyst and a teratoma.

Phillips Thygeson.

Offret, G. Primary malignant tumors of the orbital musculature. *Arch. d'Ophth.*, 1941-42, v. 4, no. 1-2, p. 1; and no. 3-4, p. 81. (See Section 15, Tumors.)

Shoji, Y. A case of primary epitheli-

oma of the meibomian gland with invasion of the orbit and destruction of the globe. *Arch. d'Opht.*, 1941-42, v. 4, no. 1-2, p. 32. (See Section 15, Tumors.)

Vancea, P. and Lazarescu. Retinal folds caused by pressure from a mucocele of the frontal sinus invading the orbit. *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 354. (See Section 10, Retina and vitreous.)

Velter, M., and Mergiot de Trigny, P. Acute unilateral exophthalmos in a newborn infant. *Bull. Soc. d'Opht. de Paris*, 1939, Oct.-Dec., pp. 569-570.

An infant, born one month prematurely developed a marked swelling of the upper eyelid, slight exophthalmos, and chemosis shortly after birth. Soon afterwards, the lower eyelid became swollen and chemosis and exophthalmos increased. Biopsy specimen revealed normal tissue, although gross inspection suggested an angioma. The cornea of this eye remained normal despite the severe protrusion. The infant presented no other signs of malformation. Morton R. Cholst.

Wright, A. D. Pulsating exophthalmos. *Proc. Royal Soc. Med.*, 1945, v. 38, July, p. 479.

A case of traumatic pulsating exophthalmos is presented. Twelve days after the accident the internal carotid artery was ligated. Five minutes later hemiplegia and aphasia developed. The ligature was removed with prompt recovery of movement and speech. After seven days the common carotid was tied and the eye rapidly returned to normal. However, its sight was lost during the time between the two operations. Morris Kaplan.

EYELIDS AND LACRIMAL APPARATUS

Desvignes, P., and Offret, G. Tumors of the lacrimal-sac region. *Arch. d'Opht.*, 1945, v. 5, no. 1, p. 25.

The diagnosis of lacrimal-sac tumor is difficult and is usually made only after invasion of surrounding structures. Two illustrative cases are reported. In the first case diagnosis of basal-cell epithelioma was made three years after removal of the sac for dacryocystitis. The authors believe it possible that the original stenosis was of neoplastic origin. In the second case the patient presented apparent mucocele of the sac with fistula formation. Tumor was suspected when the fistula failed to close normally under treatment. Microscopic examination revealed a basal-cell epithelioma with limited extension. The authors point out that lacrimal-sac tumors develop in two phases; first, dacryostenosis and dacryocystitis without unusual characteristics, and second, tumefaction. Tumor is to be suspected if the swelling is particularly hard or if there is spontaneous bleeding from the puncta. Tumors generally are not painful and there is no adenopathy. They may invade the nasal fossa, the orbit, or the skin. Phillips Thygeson.

Folk, M. R., and Brunner, H. Edema of the eyelids in infections of the paranasal sinuses. *Illinois Med. Jour.*, 1945, v. 87, May, p. 245.

Lid edema due to infections of the paranasal sinuses might be due to an osteitis of the sinus walls or to thrombophlebitis of the anastomosing vessels. The former is more frequent in old people, the latter in young ones. The

frontal sinus is scarcely developed before the seventh year of life. In young children, therefore, lid edema is caused by infection of the maxillary sinus or the anterior ethmoid. In fact, lid edema is the most conspicuous sign of ethmoiditis in infants or young children. As the phlebitis extends backwards into the orbit, symptoms like high fever, exophthalmos, meningeal symptoms may appear and give the impression of a severe illness. These symptoms, however, disappear after simple conservative measures, such as shrinkage of the nasal membrane and the administration of sulfa drugs. If, however, the infection, while spreading backwards into the orbit, causes a subperiosteal abscess, the disease will continue for a longer time, and exophthalmos, displacement of the eye, and transitory muscle paralysis will become more prominent than the lid edema. Even in these cases surgery should be postponed as long as possible and one should rely on conservative measures and sulfa drugs. If one has the chance to see the lid edema develop, some conclusions of practical importance can be drawn. Maxillary-sinus infection involves the lower lid first, frontal and ethmoidal infections involve the upper lid first. Lid edema due to dacryocystitis is localized below the inner palpebral ligament, that due to ethmoiditis is localized above the palpebral ligament and over the frontal process of the maxilla from which the edema extends outward. In frontal-sinus infection the edema starts in the mesial or lateral portion of the upper lid.

Four case histories are given.

R. Grunfeld.

Leopold, I. H., Mahoney, J. F., and

Price, M. L. Symmetric defects in the lower lids associated with abnormalities of the zygomatic processes of the temporal bones. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 210-214.

The literature is discussed and a case report is given in which symmetric defects in the outer third of each lower lid, with absence of the zygomatic processes of the temporal bones, as shown roentgenographically, occurred in a grandparent, mother, and daughter. The ancestral history of these cases suggests that the defect was hereditary and that the trait is a dominant one.

R. W. Danielson.

Nuri Fehmi Ayberk. Suppurative and cystic bilateral dacryocanaliculitis in an old trachomatous inflammation. *Göz Klinigi*, 1945, v. 3, Aug., pp. 1-4.

A woman of 55 years, with old trachoma, had a suppurative canaliculitis with cystic dilatation of both upper eyelids. The author has seen this complication in only 30 out of 1,050 patients suffering from trachoma. (References.)

TUMORS

Castañé Decoud, D. D'A. de. Choroidal melanomas. *Anales Argentinos de Oft.*, 1944, v. 5, Oct.-Nov.-Dec., pp. 123-135. (See Section 7, Uveal tract, sympathetic disease, and aqueous humor.)

Dejean, C. Unrecognized intraocular tumors. *Arch. d'Opht.*, 1941-42, v. 4, no. 1-2, p. 38.

The author calls attention to the difficulty of diagnosing intraocular tumors at onset, particularly in elderly individuals, and cites the relative frequency of tumors in eyes enucleated because of glaucoma. He reports his own series of 14 eyes, all enucleated for glaucoma. Two of these, on section, showed malignant melanoma of the choroid. The first of these was enucleated because of chronic glaucoma with repeated inflammatory exacerbations; vision was nil and the fundus could not be seen. The tumor was found to fill almost the entire vitreous cavity. In the second eye vision was likewise nil, and the fundus was obscured by a pupillary membrane. The entire vitreous was found to be replaced by a melanoma which had not been suspected.

On the basis of these two cases and a survey of the literature, Dejean reviews the objective and subjective signs of intraocular tumor. Among the subjective signs he includes localized field changes, metamorphopsia, micropsia, muscae volitantes, and phosphenes; as objective signs he describes corneal precipitates, pupillary paralysis, melanotic deposits on the iris, retinal detachment, and faulty transillumination. A sign of particular importance is the poor compressibility of the sclera over a tumor. The author stresses the frequency of tumor in progressive unilateral painful glaucoma which resists miotics.

Phillips Thygeson.

Humayer, Karl. Improvement of visual disturbances caused by pituitary tumor after mastoid operation. *Klin.*

M. f. Augenh., 1942, May-June, v. 108, p. 335.

A female of 36 years came for treatment of otitis media and beginning mastoiditis in January, 1933. Previously she had been given several X-ray treatments for a large pituitary tumor of extrasellar origin which had been diagnosed in 1929 and which had already destroyed the dorsum of the sella. Vision and bitemporal hemianopsia had improved after each treatment, but the improvements never lasted more than a few months. Mastoid operation eventually became imperative. When the necrotic parts of the bone of the sinus plate were removed the dura of the cerebellum was laid open. Five days after the operation the visual fields and the visual acuity improved, so that the patient could read again. After one year the visual acuity was 5/5 and 5/7 in the right and left eye, respectively, and the visual field of the right eye still showed a hemianopic defect for white and colors in the upper temporal quadrant. During the following eight years no further X-ray treatment became necessary, and the patient was completely free of any disturbances. The incomplete atrophy of both discs did not change. It is assumed that the success of the operation resulted from the removal of bony structures which produced a decompression of the brain, the optic nerves, and chiasm.

F. Nelson.

Lagrange, H. A case of tuberculous dystrophic osteitis of the skull. *Ann. d'Ocul.*, 1941, v. 177, no. 7, pp. 263-270.

A male 37 years of age had a tumor of the right frontal region with normal vision, a left exophthalmos with optic atrophy, and a vision of 4/200. X-ray

studies showed a rarification of the right frontal bone and a similar area in the occipital region. A tumor biopsy specimen contained giant cells, from which several tubercle bacilli were isolated. Guinea-pig inoculation tests verified the tuberculous etiology.

Chas. A. Bahn.

Monbrun, Offret, G., and Guillaume, J. Value of examination of the sheath membranes in tumors of the optic nerve. *Arch. d'Opht.*, 1945, v. 5, no. 1, p. 8.

Careful examination of the meninges of the optic nerve in nerve tumors is strongly recommended. Two cases of optic-nerve glioma are reported by way of illustration. In both, histologic study of the tumors themselves was rendered difficult because of degenerative changes in the tumor substance, but examination of the meninges revealed characteristic tumor-cell infiltration. The detailed histologic study is documented by numerous drawings.

Phillips Thygeson.

Offret, G. Primary malignant tumors of the orbital musculature. *Arch. d'Opht.*, 1941-42, v. 4, no. 1-2, p. 1; and no. 3-4, p. 81.

This extensive review in two parts is based on 25 cases from the literature, plus an additional two cases observed by the author. Five cases of fibroblastic sarcoma are described of which three were verified histologically and two were doubtful. The tumors were all in young subjects and involved three different rectus muscles. In each case diagnosis was made only after surgical removal. It was not possible to conclude as to local recurrence or metastasis, as postoperative observations were

incomplete, but it is believed that such recurrences are the rule. In the five cases the clinical signs and symptoms varied considerably, while the microscopic picture was relatively uniform.

A single case of polymorphic sarcoma with total involvement of the superior rectus in a child of two years is reported. There were ten cases of rhabdomyosarcoma. Typical and atypical forms were recognized by the microscopic appearance. Of the ten cases, seven were in infants or young children, two were in adults. Two clinical types were noted; the first became superficial early and simulated palpebral, conjunctival, or limbic lesions; the second, whose neoplastic nature was discovered only on biopsy, remained deep and was evidenced by exophthalmos. These neoplasms recur readily and frequently become generalized. Radiotherapy is of value.

Only two cases of leiomyosarcoma are reported and in both the diagnosis was open to some doubt. Seven cases of round-cell sarcoma, of which six occurred in individuals of from 32 to 61 years of age, are recorded. The clinical picture of orbital neoplasm with exophthalmos was uniform in all cases. In general these tumors are radiosensitive and have a favorable prognosis. Adequate follow-ups were not available but local recurrence was noted in only one case and was relieved by radium.

The author states that reticulosarcomas of the orbit, and particularly of the orbital musculature, are extremely rare but he reports two cases, one of which was his own. This tumor is radiosensitive and the prognosis is good.

In a general discussion of the subject, Offret stresses the fact that nor-

mal muscle function is well maintained in spite of extensive invasion of the muscles and that disturbance is generally due to nerve involvement.

Phillips Thygeson.

Shoji, Y. A case of primary epithelioma of the meibomian gland with invasion of the orbit and destruction of the globe. *Arch. d'Ophth.*, 1941-42, v. 4, no. 1-2, p. 32.

The literature on malignant tumors of the meibomian gland is reviewed and the eight cases which have been reported from Japan are described in detail. The author's patient was a woman of 69 years who had a chalazion-like nodule of the right lower lid of five years duration. This tumor slowly increased in size until it surrounded the globe, destroyed the lower lid, and invaded the lateral half of the upper lid. It had grown to the size of a man's fist. Over the temporal part of the tumor the skin had disappeared, leaving a bleeding ulcer. The tumor on extirpation weighed 48 grams and surrounded the atrophic globe. Microscopic examination showed that the tumor was an epithelioma. Its origin from the meibomian gland was well shown by the lipoidal content of the characteristic cells, demonstrated by fat stains and by the polarizing microscope. The study is well documented by photographs and drawings.

Phillips Thygeson.

Vetter, Joachim. A metastatic choroidal carcinoma from cancer of the breast in a male. *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 349.

Of the 150 cases of metastatic carcinoma of the choroid reported up to 1939 60 to 70 percent originated from primary tumors of the breast but only

once in a male. The author saw a man of 69 years in whose left breast carcinoma with metastasis in the axillary lymph nodes had been diagnosed two years previously. Operation had been refused. A large retinal detachment was found in the right eye. The eye was enucleated and the metastatic carcinoma of the choroid was demonstrated histologically. Subsequently the primary tumor was removed surgically but a roentgenogram revealed metastases in both lungs. (3 microphotographs. Bibliography.)

F. Nelson.

Wiedersheim, O. Two rare angiomatous lesions in the fundus. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 205-213.

The author reports observations on two eyes that showed a mass of dilated convoluted vessels contiguous to the disc which extended out far beyond the macula. In one of them the anomalous vessels seemed to have extended into the depths as though connected with the choroid. A year later the vessels had collapsed and the swelling in the involved area had receded, presumably as a result of strangulation from pressure which the mass itself exerted on its blood supply.

The author speculates on the relations between racemose arteriovenous aneurysm and retinal angiomatosis and their theoretical significance. (4 figures, references.)

F. Herbert Haessler.

INJURIES

Amsler, Marc. Direct ocular lesions through skiing accidents. *Bull. Soc. d'Ophth. de Paris*, 1939, Oct.-Dec., pp. 595-599.

Fourteen cases of trauma to the eyes

due to skiing accidents are discussed. Direct lesions are produced by either the ski poles or the point of the ski itself. The lesions consisted of contusions and detachments of the eyelids, paresis of the ocular muscles, exophthalmos, enophthalmos, and various injuries to the eyeball itself. Nine eyes were rendered useless. The author declares skiing a most dangerous sport.

Morton R. Cholst.

Benkwith, K. B. Eye injuries and diseases encountered during Iwo Jima campaign. U.S. Naval Med. Bull., 1945, v. 45, Sept., p. 433.

The problems of the diagnosis and treatment, and some general observations of the 81 eyes injured in the Iwo Jima campaign are presented in moderate detail. In most of these there were recent, serious trauma with multiple infective foreign bodies in the eye and the surrounding tissues. Although the eyes were observed and treated for only one to three days before evacuation to the rear, the results were dramatic. In addition to the necessary surgical treatment, most patients received large doses of sulfadiazine orally, 30,000 units of penicillin intramuscularly every three hours, and penicillin applied locally. Calcium penicillin was freshly prepared in concentrations of 10,000 units to the c.c. and used topically, injected subconjunctivally over the whole globe, injected into the vitreous body in amounts of 0.2 c.c., and used as an irrigation solution of the anterior chamber. The very excellent therapeutic results are ascribed to the routine use of these heroic measures combined with very tight pressure bandages.

Morris Kaplan.

De Saracibar, Jose M., Varices of

Gent. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Jan., pp. 50-53.

Gent described irregular dilations of the conjunctival blood vessels produced by the caustic effect of mustard gas. The author describes an eye with identical clinical picture though no history of contact with a caustic chemical could be obtained.

Jäger, A. Eye injuries caused by owls. Klin. M. f. Augenh., 1942, v. 108, May-June, p. 346.

A man of 55 years was attacked by an owl. In the right eye the lens became partially dislocated; the left eye sustained a conjunctival and scleral non-perforating wound. Vision in the right eye was first considerably reduced, but both eyes recovered full vision eventually. (Reference.)

F. Nelson.

Rouquier, A. Amaurosis and amblyopia as a result of posttraumatic reflex sympathetic disturbances of the face. Presse Medicale, 1945, July 28, p. 412.

The case of a soldier wounded by a mine explosion is reported. About 15 small pieces of stone had penetrated the skin of the face, chiefly on the left side. None of these had struck the eyes, penetrated the orbits, or damaged the optic nerves. The soldier had at no time lost consciousness and had not sustained a brain concussion. A bilateral blepharospasm, much more marked on the left side, developed during the days following the explosion, and at the same time the left eye became almost totally blind while vision in the right dropped to 3/50. The left pupil was smaller than

the right but reacted normally. Neurologic examination revealed sympathetic disturbances more marked on the left side. The electro-encephalogram showed alterations localized to the two prerolandic regions, more marked on the left side.

Treatment consisted in the injection of acetylcholine and in cocaine applications to the middle turbinates. Under this regime the patient's difficulties slowly resolved so that vision had become normal in both eyes and the blepharospasm had disappeared two and a half months after injury. Repeated electroencephalograms continued to show abnormalities, however, but their extent diminished steadily. Rouquier states that this would have been called a case of hysteria a few years ago but that neurologists now recognize the reflex sympathetic nature of the lesion. The amblyopia is believed to be due to circulatory changes in the retina. Phillips Thygeson.

Sédan, J. Total, unilateral, external ophthalmoplegia following electric short circuit. *Ann. d'Ocul.*, 1942, v. 178, no. 2, pp. 64-71.

No similar observation has been reported. An electrician, 27 years of age, was badly shocked when a short circuit occurred in a transformer which reduced a current from 5,000 to 110 volts. A total external unilateral ophthalmoplegia resulted, with partial paralysis of the seventh nerve. Improvement began about the forty-fifth day with slight restoration of the sixth-nerve function. All muscular function was entirely restored in four months.

Chas. A. Bahn.

Valerio, M. Two rare cases of juvenile degeneration of the cornea. *Bull.*

Soc. d'Opht. de Paris, 1939, Oct.-Dec., pp. 612-614.

Two young men, 25 years of age, with no significant family history, each had a disciform corneal opacity. In one of them microscopic examination revealed gray-yellow polygonal elements in Bowman's membrane which had the appearance of a mosaic. In the other, microscopic examination revealed crystalloid deposits in the parenchyma of the cornea. The author believes that senile alterations can take place at an early age as an expression of a recessive hereditary degeneration.

SYSTEMIC DISEASES AND PARASITES

Balza, Jorge F., and García Querol, Armando. Ocular changes in pregnancy. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, April, p. 216; June, p. 311; July, p. 356; Aug., p. 411; Sept., p. 464.

This is a very exhaustive review of the subject, appended by 65 detailed case histories and presented in the following sections: general considerations, glaucoma and pregnancy, myopia and pregnancy, intraocular pressure in pregnancy, pressure of the central retinal artery in pregnancy, visual fields in pregnancy, accommodation and light sense in pregnancy, ocular changes in septic abortion, ocular changes in hyperemesis gravidarum, retinal detachment in pregnancy, sudden blindness in pregnancy, hypertensive retinosis in pregnancy, ocular changes during labor and puerperium, case reports, and sum-

mary. From their studies the authors arrive at the following conclusions:

(1) Glaucoma is extremely rare in pregnancy. (2) Myopia may appear or if present may increase during pregnancy. Calcium metabolism probably plays an important role in this connection. (3) Intraocular pressure was found to be within normal limits. (4) The pressure of the central retinal artery was normal in all cases with normal systemic blood pressure and was increased in arterial hypertension. (5) No definite visual-field defects were found. (6) No investigation of accommodation and light sense in pregnancy could be carried out. (7) No ocular complications were observed in septic abortion. (8) Hyperemesis gravidarum was complicated with retinal hemorrhages. (9) Retinal detachment during pregnancy may be of three types: (a) ordinary retinal detachment occurring during pregnancy without symptoms of toxemia, requiring ocular surgery by the standard procedures; (b) retinal detachment with symptoms of toxemia, a typical complication with characteristic symptoms requiring immediate therapeutic abortion; and (c) retinal detachment occurring during or after labor in which a predisposing cause such as myopia is usually present. (10) Sudden blindness in pregnancy may be due to hysteria, but is usually associated with eclampsia, when the blindness may last hours or even days. (11) Hypertensive retinosis is the most frequent ocular complication of pregnancy. It appears usually during the second half. Its earliest signs are arteriolar spasms and increased pressure of the central retinal artery. If it appears before the fetus is viable and there is no improvement with systemic treatment, therapeutic abortion must

be resorted to. When the retinosis appears after viability, if the retinal lesions are discrete and show a tendency to regression under treatment, it is advisable to await the termination of pregnancy; on the other hand, if the retinal lesions are extensive, with no improvement under systemic treatment, the pregnancy should be interrupted. (12) The normal eye tolerated pregnancy well. (1 diagram, 2 color fundus pictures, 8 fundus photographs, 4 tables, bibliography.)

Giqueaux, R. E., and Ochoa, R. G. Ocular myiasis. *Anal. Argentinos de Oft.*, 1944, v. 5, July-Aug.-Sept., pp. 79-83.

A 3-months-old infant is discussed from whose right eye many larvae were removed. These worms presented themselves only when exposed to chloroform fumes. There was subacute

conjunctivitis, with the larvae residing in the folds of the plica semilunaris. A discussion of general myiasis and ocular myiasis follows. (2 illustrations.)

Edward Saskin.

McGraw, James L. Marfan's syndrome with unusual complications. Arch. of Opht., 1945, v. 34, Aug., pp. 112-113.

The author reports a case of Marfan's syndrome, occurring in a family in which three of six children were mentally deficient, and one of the three showed other congenital defects, among them, ectopic lenses.

The patient, a girl, had ectopic lenses, apathetic expression, prominent ears, thin, flat chest, winging of the scapulas, and spinal curvature. The tension was elevated in one eye with partial dislocation of the lens but was normal in the other eye in which the lens was completely dislocated. Seven months after a lens extraction from one eye a large anterior-chamber cyst developed associated with a rise in tension. The cyst was successfully destroyed by flushing it with 3.5 percent iodine solution. John C. Long.

Mukerji, A. K., and Bhaduri, N. V. Gnathostome infection of the eye. Indian Med. Gazette, 1945, v. 80, p. 126.

A Bengalee Hindu male 26 years of age complained of a dull, aching pain on the left side of his nose and left frontal region for a week. Next day a swelling appeared on the left cheek which spread to the left lower eyelid. Physical examination revealed orbital cellulitis, but normal vision. Two days later the cellulitis improved, the vision, however, dropped to perception of hand movement. Hemorrhages in the retina and in the vitreous were noted. Three

days later a severe iritis with small grey nodules on the iris developed. The nodules soon disappeared but a definitely motile pigmented mass made its appearance on the iris. From the angle of the anterior chamber a worm of 2 1/2 cm. length was removed which belonged to the genus *Gnathostoma* (Nematoda). The parasite resembled the species described by Maplestone and differed somewhat from *G. spinigerum* and *G. hispidum*.

The parasite, and the life cycle of *G. spinigerum* are described. In Bengal men usually acquire it by eating raw or dried fish. R. Grunfeld.

Pérez Vélez, A. A. Oral infection and ophthalmology. Rev. Oto-Neuro-Oft., 1944, v. 19, Oct., pp. 141-143.

A concise, informative discussion of dental anatomy and physiology is presented. The intimate relationship between the orbital and dento-buccal vascular, lymphatic, and nervous systems may account for ocular disease due to dental foci of infection. In certain ophthalmic problems, it is wise to have a complete dental examination, including X-ray study, and to remove immediately any infections in the mouth. Edward Saskin.

Radnot, Magda. Eye findings in Cushing's disease. Ophthalmologica, 1942, v. 104, Dec., pp. 301-307.

Adenomata of the anterior lobe of the hypophysis may compress the optic nerve and lead to bitemporal hemianopsia, edema of the retina, and retinal hemorrhages. The latter can be the result of arterial hypertension. In addition to these findings the author stresses the possibility for increased intraocular pressure due to disturbance

of the endocrine system. Three cases of Cushing's disease with swelling of the face, decrease in calcium of the bones, low sugar threshold, and arterial hypertension are reported. Two of them showed elevation of the intraocular pressure. Max Hirschfelder.

Schmelzer, Hans. The problems of ocular tuberculosis and its treatment. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Jan., pp. 24-42.

There are still many unsolved problems in the field of ocular tuberculosis. Cases of true caseous ocular tuberculosis are extremely rare. The great majority of chronic inflammatory processes in the eye are not true tuberculous affections but are tuberculoallergic. Occasionally allergy to other organisms is causative. The treatment, then, is directed toward desensitization by specific and nonspecific therapy. Rest and diet are fundamental adjuvants. Graduated injections of tebe-protein are preferred for specific therapy, guided by frequent blood counts which indicate the state of allergy by the white-cell picture. As nonspecific therapy, copper or gold is used intravenously, often with the addition of calcium. J. Wesley McKinney.

Schwartz, A. R. Exophthalmic goiter in children. Arch. of Pediatrics, 1945, v. 62, May, p. 214.

A case of exophthalmic goiter in a child two years and three months of age is reported because of the rarity of the condition. R. Grunfeld.

Shannon, E. W., and Soloman, J. Bilateral temporal arteritis with complete loss of vision. Jour. Amer. Med. Assoc., 1945, v. 127, March 17, p. 647.

In a patient with acute bilateral tem-

poral arteritis all vision in both eyes was promptly lost. Resection of the affected portions of the arteries relieved all symptoms but the loss of vision. Fundus studies showed venous engorgement, blurred disc margins, papillary and retinal edema, threadlike arteries, and some minute hemorrhages. The cause of the ocular involvement is not clearly understood though it is suggested that the retinal artery undergoes the same pathologic processes which are found in the temporal artery.

Morris Kaplan.

Spaeth, E. B., and Krewson, W. E. III. Arteriovenous aneurysms in the region of the circle of Willis. Jour. Internat. College Surg., 1945, v. 8, July-Aug., p. 313.

An anatomic and physiologic review of the circle of Willis is presented with stress on its ophthalmologic aspect. There are five types of aneurysm of this structure and all of them give rise to ocular signs and symptoms. The diagnosis is difficult in all types and most often is not made until after rupture and death. Arteriosclerosis, trauma, and syphilis are the etiologic agents in most cases. Arteriovenous aneurysms, on the other hand, are relatively easily diagnosed and offer considerably more hope of repair. Exophthalmos with pulsation and bruit are the cardinal and almost constant symptoms. The therapy of choice is ligation of the common carotid artery with subsequent ligation of the internal carotid. (Bibliography of 363 references.) Morris Kaplan.

Spies, T. D., Perry, D. J., and others. Ocular disturbances in riboflavin deficiency. Jour. Lab. and Clin. Med., 1945, v. 30, Sept., p. 751.

The results presented are of a two-

year study of riboflavin deficiency conducted in the Nutrition Clinic at Hillman Hospital of Birmingham, Alabama, by the Departments of Internal Medicine and Ophthalmology of the University of Cincinnati. Ninety percent of patients reporting to the clinic suffered dietary deficiency and of these 70 percent complained of visual disturbances. Five hundred eye patients were treated, of which 300 are reported in this paper. The general symptoms were nervousness, insomnia, headache, burning and aching of legs and feet, burning and cramping of stomach, constipation, burning of the skin, and general inability to do physical work. The ocular symptoms were itching and burning of the eyes, failure of visual acuity, photophobia, lachrimation, conjunctivitis, and night blindness. Dilatation of conjunctival and corneal vessels, corneal ulceration (53 percent interstitial keratitis (60 percent) and pterygia (50 percent) were found. In spite of these signs and symptoms no pathognomonic picture of the disease could be made. The pathogenesis of the deficiency is not understood but the response to riboflavin was unmistakable. Three detailed case reports are given to show that the response to riboflavin in advanced stages of the disease was dramatic. Of the 300 patients 72 percent were able to return to work after months or years of idleness. (Bibliography.)

Morris Kaplan.

Stine, G. H., and Draper, P. **Horner's syndrome.** *Rocky Mountain Med. Jour.*, 1945, v. 42, July, p. 504.

A review of the anatomy and the etiologic factors involved in Horner's syndrome is presented. The symptoms are described. The differential diag-

nosis of the spastic miosis by means of an analysis of the pupillary responses to autonomic drugs such as acetylcholine and adrenalin is presented in detail. In a man who developed the syndrome after mumps encephalitis complicated by a head injury, the instillation of adrenalin was followed by a temporary recovery. The lesion was postganglionic, probably the result of a thrombosis of the internal carotid artery.

Morris Kaplan.

Taylor, W. O. G., and Fergusson, A. G. **Dermatitis from wearing Army spectacles.** *Brit. Med. Jour.*, 1945, July 14, p. 40.

Six cases of dermatitis are presented. The British Army spectacle frames are made of nickel silver, which is an alloy of nickel, copper, and zinc and is plated with nickel. In each case the dermatitis commenced promptly upon wearing the glasses, occurred in the areas of contact with the frames and healed promptly after removal of the glasses or a change of the frame. It was concluded that the dermatitis was an allergic reaction to ionized nickel which was freed by electrolysis in the presence of acid sweat aided by the body heat.

Morris Kaplan.

Valenta, A. **Sudden bilateral blindness of luetic origin.** *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 339.

A 53-year-old male lost vision in both eyes within 24 hours. Only a slight remnant of light perception was left which was completely lost two days later. Pupils were wide and inactive, but both eyes were otherwise normal. Neurologic examination and roentgenograms were negative. The Wassermann reaction in blood and

spinal fluid was strongly positive. Two days later bilateral papillitis developed with retinal hemorrhages in the left eye. Antisyphilitic treatment and vitamin-B injections were started immediately. Sixteen days after the onset of the blindness light perception returned and nine days later fingers could be counted. Optic atrophy developed. Subsequent improvement of functions could not be followed up since the patient withdrew from further observation. It might be assumed that a gumma had formed in the chiasm, or that a non-specific agent had caused a transverse optic neuritis in the body which had been rendered less resistant by the chronic infectious syphilitic process.

F. Nelson.

HYGIENE, SOCIOLOGY, EDUCATION,
AND HISTORY

Boshoff, P. H. Blindness and diseases of the eye in South Africa. South African Med. Jour., 1945, v. 19, May 12, p. 148.

In 1938 the ratio of blind per 100,000 in the United States was 51.8 while in South Africa it was 400 for the nation and reached 2,000 in some districts. He states the amount of money spent for pensions in a rather makeshift system of registration and insists that if some of that money were used to subsidize well-trained ophthalmologists who would practice among the natives, the figures of blindness could be greatly reduced. The plea continues for postgraduate ophthalmologic facilities in their two medical schools, since no such facilities exist in the entire nation.

Bücklers, M. Ophthalmologic race hygiene according to Lisch. Klin. M. f.

Augenh., 1942, v. 108, March-April, pp. 155-160.

Apparently Lisch expressed some extreme views on the subject. Bücklers criticizes him most scornfully and analyzes the individual case histories which Lisch used as illustrations. (References. F. Herbert Haessler.

Chenoweth, C. Rehabilitation of the deaf and blind. Jour. Iowa State Med. Soc., 1945, v. 35, Oct., p. 392.

The newly blinded casualty is assured a psychologic and emotional support by special consultant at the first hospital of residence. A temporary training program is arranged to bridge the time until the newly blinded soldier is sent to one of two special centers. At the center the soldier is taught how to dress and shave, how to feed and care for himself. He is taught the use of a typewriter. The talking book and radio offer much enjoyment before he learns Braille. Occupational therapists teach him to use his hands, to develop new skills and dexterity and thus assist in restoring confidence through useful work. When the patient has learned to get about readily he is encouraged to enlarge his social contacts.

Experience shows that only ten percent of the blind can use Seeing Eye dogs advantageously. Many blinded soldiers will develop the ability to get about inconspicuously with a minimum of assistance and a skillfully used cane.

Following the initial training, the direction of schooling depends greatly on a patient's native ability, intelligence, and past education. The government will send any blind man through college who is able to qualify.

Cowen, J. P. Optical service units of the Navy. *War Med.*, 1945, v. 8, July, p. 18.

The two types of optical units used by the Navy are described. The large, permanent-base type, and the smaller, semipermanent mobile type. By their use the supplying, replacing, and repairing of spectacles has been carried directly to personnel in the field. They do no examining or treating but satisfactorily produce the average, single-vision spectacles required by the Navy.

Eames, T. H. Eyes of premature children. *Amer. Jour. Ophth.*, 1946, v. 29, Jan., pp. 57-63.

Feiman, E. M. Rehabilitation of the blind. *Indust. Med.*, 1945, v. 14, Aug., p. 649.

In the Timken Roller Bearing Company of Canton, Ohio, totally blind employees check bearings which must be accurately ground to one twenty-five millionth of an inch. These bearings are checked in an electronic device which for the sighted operator automatically switches on lights of various colors to denote under, over, or acceptable dimensions. For the blind operators, the company invented a sound detector, which emits notes of different pitch from a small speaker mounted on the back of the chair of the operator. The Timken Company offers this apparatus without royalties to any industry willing to employ the blind for such work.

Keller, P. Blindness in Tonkin. *Arch. d'Ophth.*, 1941-42, no. 3-4, v. 4, p. 101.

Visitors to Indo-China are struck by the frequency of blindness among the seven million inhabitants of Tonkin, but no statistics as to cause and frequency have been available. Keller, who is director of the Ophthalmological Institute of Hanoi, has analyzed the findings in 14,000 patients drawn from

a population of approximately 100,000. The gonococcus proved to be the principal cause of blindness and the author has outlined a detailed plan of prophylaxis whereby each case of purulent ophthalmia could be detected early and treatment started. Other causes of blindness are analyzed in chart form and the total number of totally blind in the province is estimated to be 22,470 with 30,030 blind in one eye.

Phillips Thygeson.

Kranz, H. W. Indications for sterilization of individuals with cataract. *Klin. M. f. Augenh.*, 1942, v. 108, March-April, pp. 145-155.

Kranz, not an ophthalmologist but director of the University Institute for race hygiene at Giessen, outlines the principle which underlies a decision to bring about sterilization of an imperfect individual. He discusses each type of cataract and points out that less than ten percent justify sterilization.

Pepper, O. H. P. Modification of a blood pressure apparatus for use by the blind. *Arch. of Ophth.*, 1945, v. 34, Aug., pp. 113.

This is a description of an apparatus developed by J. O. Kleber of the American Foundation for the Blind. It consists of a modification of the Tycos spring sphygmomanometer with a plastic bristle and elevated pegs so that the instrument may be used by the blind. Two illustrations.

John C. Long.

Polack. Tscherning and his work. *Annales d'Ocul.*, 1940, v. 177, May, pp. 179-187.

Tscherning died on September 1, 1939, the day of the beginning of World War II. Polack's obituary has only just become available for American readers.

Born in 1854, on a Danish island, Tscherning's early thesis on the etiology of myopia led to his appointment as Assistant Director in Javal's laboratory at Paris. He obtained his Doctorate in Medicine in 1887, with a thesis on the law of Listing; was naturalized a Frenchman, was made Chevalier de la Légion d'Honneur, and in 1910 was made Professor at the University at Copenhagen, resuming his Danish nationality. In 1890, Tscherning presented to the Société Française d'Ophthalmologie a new apparatus called "ophthalmophakometer," the purpose of which was to determine the radii of curvature of the crystalline lens, its distance from the cornea, and the form of its posterior surface. In the same year he presented a study on the in-

fluence of spherical aberration on the refraction of the eye, a subject which had not previously received attention. In 1892 he published the first results of his researches on accommodation. His lessons on physiologic optics, delivered at the Sorbonne, were published in 1898. In 1904 he presented to the International Congress of Ophthalmology the first results of his researches on color vision, in which he questioned the adequacy of Young's theory of color vision. (A 2-page chronologic list of Tscherning's works; portrait.)

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Deringer, M. K. The results of homoplastic, heteroplastic, and xenoplastic transplantation of the optic vesicle in *Triturus* and *Rana*. *Jour. Nat. Cancer Inst.*, 1945, v. 5, June, p. 437.

Experiments performed by the author confirmed the results of previous investigators that in all amphibians at the tail-bud stage the optic vesicle has complete powers of self-differentiation; that is, when it is transplanted to an unusual position, it is able to form an eye with all its characteristic parts, usually in their normal relations. Occasionally, however, various abnormal relations were established. Distortion of the retinal layer, displacement of the lens, and failure of the optic nerve to connect with the host brain were common. The abnormal relations were fewer in homo- and heteroplastic but more frequent in xenoplastic (between individuals of widely distant species) transplantation. The transplanted eyes had a normal, although slightly smaller, appearance and the optic nerves were connected with the brain. In xenoplastic transplantation the transplanted tissue became differentiated into retina and lens, but underwent degeneration and in some cases disappeared entirely.

Dr. John Walter Webb, Indianapolis, Indiana, died October 9, 1945, aged 64 years.

Dr. Clyde L. Welsh, Seattle, Washington, killed in action December 15, 1944, aged 45 years.

Dr. Albert A. Yungblut, Cincinnati, Ohio, died August 21, 1945, aged 73 years.

MISCELLANEOUS

PRECEPTORSHIPS

In regard to the substitution of a preceptorship for residency in an ophthalmic hospital, the American Board of Ophthalmology has always accepted such training in favorable cases. During the present overcrowding of facilities, the Board expects to take a liberal attitude regarding the requirements for training.

It should, however, be pointed out that neither a residency nor a preceptorship suffices in itself to meet the requirements of the Board. Each case will still be judged on its merits in determining fitness for examination.

In entering upon a preceptorship certain conditions should be kept in mind. First the student will profit most after a sound course in the basic sciences of physiology of the eye and of vision, optics, pathology, bacteriology, chemistry, pharmacology, the relation of the eye to general disease, anatomy, embryology, and neurology.

This is essential for a residency, more so for

a preceptorship. While men have been accepted from preceptors not diplomates of the Board, it is obvious that the Board has more information about those teachers who have passed its examinations.

Any preceptor should understand that he is assuming a responsibility in taking a student and is not merely obtaining help in the drudgery of his office. He should be willing to give time to clinical training and the use of apparatus, slitlamp, ophthalmoscope, tonometer, and to directing the student's practice in surgery on animal eyes, assisting in operations, and ultimately in performance of them.

To cover the same amount of ground will take much longer in a preceptorship than in a residency, and students should accept opportunities to take hospital positions of all sorts as they become available.

S. Judd Beach, M.D., Secretary.

Emory University will celebrate the one hundredth anniversary of the birth of Abner Well-born Callhoun, M.D., LL.D., born April 16, 1845, died August 21, 1910, the first professor of ophthalmology of the Atlanta Medical College.

You are cordially invited to be the guest of Emory University at an Ophthalmological Seminar to be held in Atlanta on April 4, 5, and 6, 1946.

PROGRAM

Thursday evening, April 4, 1946, ACADEMY OF MEDICINE. 6:30: Buffet supper; 7:30: Dr. James Edgar Paullin, "Dedication of Auditorium;" 8:00: Dr. Frank B. Walsh, "Myasthenia gravis;" 9:00: Dr. Walter I. Lillie, "Medical ophthalmology."

Friday morning, April 5, 1946, GRADY HOSPITAL. 10:00: Dr. Walter I. Lillie, "Diplopia;" 11:00: Dr. William Benedict, "The clinical meaning of exophthalmos." Luncheon (Guest of Grady Hospital).

Friday afternoon, ACADEMY OF MEDICINE. 3:00: Dr. Derrick Vail, "Eye changes in diabetes;" 4:00: Dr. Frank B. Walsh, "Naso-pharyngeal tumors;" 6:30: Dinner, Biltmore Hotel (Guest of Emory University).

Friday evening, ACADEMY OF MEDICINE. 8:00: Dr. Parker Heath, "Ocular therapeutics in glaucoma;" 9:00: Dr. John Dunnington, "Treatment of detachment of the retina."

Saturday morning, April 6, 1946, ACADEMY OF MEDICINE. 10:00: Dr. William Benedict, "Glaucoma in diabetes;" 11:00: Dr. John Dunnington, "Surgical treatment of the vertical deviations." Luncheon, Biltmore Hotel (Guest of Department of Ophthalmology).

Saturday afternoon, ACADEMY OF MEDICINE. 2:30: Dr. Parker Heath, "Random notes on ocular surgery;" 3:30: Dr. Frank B. Walsh, "Ocular signs of subdural hematoma;" 4:30: Dr. Walter I. Lillie, "The clinical diagnosis of retrobulbar neuritis."

Saturday evening, ACADEMY OF MEDICINE. 8:00: Dr. William Benedict, "Preparation of the patient for

cataract operation;" 9:00: Dr. Derrick Vail, "The circulation of the optic nerve and its influence on disease." Dr. Eugene Stead, Dean, 50 Armstrong Street, S.E., Atlanta, Georgia.

The University of Glasgow, Department of Ophthalmology, announces the following series of spring meetings:

During April and May a series of meetings will be held in the Department on Wednesdays at 8:00 p.m. The general arrangements will be similar to the series held last year. Tea will be served after the paper and a discussion will follow. The meetings will be open to all medical practitioners and senior students interested in Ophthalmology.

April 3d, "Industrial ophthalmology," by Prof. W. J. B. Riddell.

April 10th, "Keratoconjunctivitis," by Dr. I. C. Michaelson.

April 17th, "Concussion injuries of the retina," by Dr. A. M. Wright Thomson.

April 24th, "Ocular tuberculosis," by Professor Lowenstein.

May 1st, "Ocular vitamin deficiency," by Dr. J. D. Fraser.

May 8th, "Capillary fragility," by Dr. H. N. Munro.

All cases of legal blindness in New York State must be reported to the Commission for the Blind of the State Department of Social Welfare in accordance with a recent amendment to the act creating the New York State Commission for the Blind. It is now the duty of every health and social agency, attending or consulting physician, or nurse to report to the State Commission for the Blind, in writing, the name, age, and residence of persons who are blind within the definition of blindness and to furnish such additional information as the Commission shall request for registration or prevention of blindness.

This law supplements the mandated responsibility of the Commission for the Blind, Section 8774, Title 24, Chapter 3 of the Unconsolidated Laws to maintain a complete register of the blind in the State of New York which shall describe the conditions, cause of blindness, capacity for education, and industrial training of each, with such other facts as may seem to the Commission to be of value.

Data as required by the Commission for the Blind will further the State's effort to prevent blindness through a comprehensive knowledge of the facts relative to the causes of blindness. This information will also aid in the earlier recognition and detection of cases where remedial measures for restoration of vision are still possible. Likewise, those who may desire the services of the Commission for the Blind will be benefited through acquaintance with the opportunities available to which they are entitled.

Legal blindness is defined as total blindness or impaired vision of not more than 20/200 visual acuity in the better eye and for whom a diagnosis and medical findings show that vision cannot be improved to better than 20/200; or who has loss of vision due wholly or in part to impairment of field vision or to other factors which affect the usefulness of vision to a like degree.

Apparent blindness should also be reported even though not based on an eye examination.

For reporting blanks, please address the Commission for the Blind, 205 East 42d Street, New York 17, New York.

The following resident lectures in ophthalmology were held in New York City in February, 1946: at the Manhattan Eye, Ear, and Throat Hospital on February 1st and 8th: "Sulfonamides in ophthalmology," by Dr. L. Von Sallmann; "Allergy in ophthalmology," by Dr. Robert Cooke. At the New York Hospital on February 15th and 22d: "Syphilis of the eye and its treatment," by Dr. Walsh McDermott; "Local anesthesia in ophthalmology," by Dr. Walter S. Atkinson.

AMERICAN ORTHOPTIC COUNCIL

Examinations for Technicians

The next examination by the American Orthoptic Council will be held in September-October, 1946.

The written examinations will be held at various cities in the country on Friday, September 6, 1946. Only those passing the written examinations will be permitted to take the oral and practical tests, to be given in Chicago, Saturday, October 12, 1946.

Applications on official forms must be received before July 1, 1946.

Address the American Orthoptic Council, 23 East 79th Street, New York 21, New York.

It has been announced recently that the Helen Keller Committee on the Deaf-Blind has been formed as a department of the American Foundation for the Blind, 15 West 16th Street, New York 11, New York. The committee has the following objectives: (1) To improve educational methods for the deaf-blind on an individual basis to provide greater self-resourcefulness, thus compensating for limited contacts with others. (2) To find a shorter and more rapid manual language to speed communication with family and friends. (3) To obtain greater vocational opportunities for the deaf-blind in workshops for the blind and in private industry. (4) To increase the social relationships of the deaf-blind by developing special activities for them and by devising ways to permit them to participate in usual recreations.

SOCIETIES

The annual two-day meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology will be held at the Merion Golf Club outside of Philadelphia on Wednesday and Thursday, April 24 and 25, 1946. For detailed information address: Dr. Paul C. Craig, 232 North Fifth Street, Reading, Pennsylvania.

PERSONALS

Dr. Brittain Ford Payne has resumed the practice of ophthalmology, by appointment, at 17 East 72d Street, New York 21, New York.
- Dr. L. Conner Moss announces the reopening of his office at 1705 Rhode Island Avenue,

N.W., Washington, D.C., specializing in ophthalmology.

Drs. Trygve Gundersen and Joseph M. Clough announce their return to the practice of ophthalmology at 101 Bay State Road, Boston 15, Massachusetts.

Dr. Arthur M. Culler announces his return to the private practice of ophthalmology in the offices formerly occupied by Dr. Albert D. Frost at 150 East Broad Street, Columbus 15, Ohio.

Dr. M. W. Nugent has returned to the private practice of ophthalmology at 1930 Wilshire Boulevard, Los Angeles 5, California.

P PLASTIC ARTIFICIAL EYES

are here!

THOUSANDS OF
THESE EYES HAVE
BEEN FITTED TO
PATIENTS ON THE
RECOMMENDATION
OF EYE PHYSICIANS

SERVICE TO PHYSICIANS

Eye physicians are invited to contact us regarding patients for whom plastic eyes offer apparent advantages. Our pamphlet of instruction for ordering Gougelman perfected plastic eyes gratis on request.

Plastic artificial eyes are the result of years of scientific research, and have now been perfected to offer many advantages never before possible. Made of a fine acrylic compound, they are non-shatterable . . . will not discolor, become brittle, roughen, crack or explode. Anatomical shapes are possible and highly desirable in accident cases due to chemical burns, causes incident to war, deformed or shrunken globes and many other similar cases. Absorbing more light and reflecting less than glass, they are more life-like in appearance. Plastic eyes are not chemically affected by eye socket secretions. Write us for further details on the new plastic artificial eyes.

RELATION OF THE EYE TO IMMUNITY IN SYPHILIS, WITH
SPECIAL REFERENCE TO THE PATHOGENESIS OF
INTERSTITIAL KERATITIS*

ALAN C. WOODS, M.D., AND ALAN M. CHESNEY, M.D.

Baltimore, Maryland

In the course of a long-term study of the general problem of immunity in experimental syphilis by one of us (A. M. C.), a detailed study of the role of the eye, and especially of the cornea, in immunity to syphilitic infection was undertaken. This investigation appeared pertinent because the older literature on this subject consists of reports of experiments which were carried out at a time when our information concerning the development of immunity in syphilis was fragmentary, particularly in relation to the time required for its development, and which therefore lack data essential to their proper interpretation. For this reason the problem was reinvestigated in the light of what is now known of the development of acquired immunity to syphilitic infection. The results of these investigations have all been reported in detail elsewhere and the literature on the subject reviewed.^{1, 2, 3} However, since certain points were uncovered by these experiments which may be of especial interest to ophthalmologists, and which may cast some light on the pathogenesis and certain clinical characteristics of interstitial keratitis, these experiments are again reported here in summary and their possible relation to interstitial keratitis is discussed.

The whole subject of immunity in syph-

ilis has been reviewed by one of us elsewhere⁴ and need not be discussed at length in this communication, but perhaps a brief summary of the present status of our knowledge in this field may be pertinent in the present discussion.

It is generally recognized that a rabbit infected with syphilis by intracutaneous or intratesticular inoculation gradually acquires a resistance against a second infection with the homologous strain of treponemes. This resistance is imparted to the skin and to the testis not previously inoculated. It is therefore a general or systemic immunity, and is effective against really massive doses of the homologous strain of organisms. It is somewhat slow in developing but is firmly established by the end of the third month after inoculation. If treatment with arsphenamine is given early in the course of the infection and in amounts sufficient to eliminate it, the development of immunity is interfered with, but if treatment is postponed until after the third month—that is, until after the immunity to the homologous strain of treponemes has been established—the immunity persists for an indeterminate period even if the animal is given amounts of arsphenamine sufficient to eliminate the original infection. In other words the immunity does

* From the Wilmer Ophthalmological Institute and the Syphilis Division of the Medical Clinics, the Johns Hopkins University and Hospital. This paper was prepared for the 1945 meeting of the Association for Research in Ophthalmology which meeting was cancelled. The paper was delivered in January, 1946, before the Research Study Club at Los Angeles, California.

not appear to be due to a continuing first infection, as some have supposed, but continues to be present in the absence of infection.

The mechanism of this immunity is not clearly understood. It was formerly thought to be cellular in character largely because of the difficulty in demonstrating protective antibodies in the circulating blood, but more recently evidence has been accumulating which indicates that a humoral factor is involved,⁵⁻¹⁰ and this factor may well prove to be the paramount if not the only factor.

The extent to which the eye shares in the development of the immune state during the course of syphilitic infection was the principal theme of our investigations. As has been stated, this question had previously engaged the attention of others, but an examination of the older literature revealed gaps in the experimental data which made it difficult to interpret many of the experiments, so that in the end one was left with too few experiments and too few animals upon which to formulate an altogether satisfactory answer to the question. For a review of this older literature, the reader is referred to our previous papers.

The experiments here reported in summary were carried out over a period of years, and not concurrently, because of lack of sufficient cage space for the experimental animals.

The specific questions which we have investigated are as follows:

I. To what extent does the cornea participate in the general resistance which develops during the course of a syphilitic infection?

II. Does a primary syphilitic infection in the cornea give rise to a general systemic infection, and does it impart to the other tissues of the body the same resistance to reinfection which develops when the primary focus is located in other tissues?

III. Does a local syphilitic infection in the cornea produce a local immunity of the cornea to reinfection?

IV. Having determined that the cornea does not regularly participate in the immunity that follows a systemic syphilitic infection, the following question was investigated: Is the local avascularity of the cornea responsible for the failure of that structure to become immune during the course of a syphilitic infection produced by inoculation elsewhere than in the cornea?

TECHNIQUE

The technique of the various experiments performed in the investigation of these four questions has been reported in detail in our previous papers. The number of test rabbits used in each experiment varied from a minimum of 12 to a maximum of 35. For every test animal used, one control animal was inoculated in order that the test and control groups would be strictly comparable. The Nichols strain of treponemes was used in all experiments. After the primary inoculation, a sufficient time was allowed for the inoculated animals to develop a full immunity before treatment with arsphenamine was begun, the time between primary inoculation with treponemes and the first arsphenamine treatment being from 163 to 217 days in the different experiments.

All ocular inoculations were intralaminar injections of the cornea with the exception of one series inoculated in the anterior chamber. The pattern of ocular reaction which followed these injections was the same in both the reacting immune rabbits and in nonimmune controls, differing in the different series of rabbits only in the length of the incubation period and the intensity of the ocular lesion. Four types of ocular reactions were noted.

The first of these, which occurred in

Figs. 1-6 (Woods and Chesney). Response of rabbit eye to inoculation with treponemes. Fig. 1, Early corneal infiltrate. Fig. 2, Spreading corneal infiltrate. Figs. 3 and 4, Experimental interstitial keratitis with vascularization. Fig. 5, Primary syphilitic nodule at limbus. Fig. 6, Primary syphilitic nodule in center of cornea.

about 40 percent of the injected rabbits, was a typical interstitial keratitis, beginning as small corneal infiltrates which often had no relation to the site of the corneal puncture. These infiltrates increased in size, coalesced, and the eye developed an ordinary syphilitic keratitis, with pericorneal congestion, vascularization of the cornea from both the super-

Fig. 7 (Woods and Chesney). Central interstitial clouding of cornea without ciliary congestion and slight vascularization.

ficial and deep loops, and an associated iritis. Clearing of the corneal infiltration began with the completion of the vascularization phase (figs. 1, 2, 3, 4).

The second type of reaction was distinguished by the early development of an elevated yellowish nodule at the limbus. This was accompanied by an inflammatory reaction and followed by the development of an interstitial keratitis similar to that already described. This primary nodule was observed in about 50 percent of the reacting rabbits (fig. 5).

The third type of reaction was similar to the second type with the exception that the primary nodule occurred in the center of the cornea (fig. 6). This produced a weakness of the corneal parenchyma and usually resulted in a corneal ectasia.

The last type of reaction was peculiar. It consisted in a deep, gradually developing, central cloud in the cornea, with a remarkable absence of both ciliary congestion and corneal vascularization. It was comparatively rare, being observed in slightly less than 3 percent of the injected animals (fig. 7).

RESULTS

I. The first question—To what extent does the cornea participate in the general resistance which develops in the course of a syphilitic infection?—was investigated in three different experiments. The general plan of the experiments was as follows: The test rabbits were inoculated intratesticularly or intracutaneously, and the resulting syphilitic infection allowed to run its course until full immunity had presumably developed. They were then treated with arsphenamine and after the completion of treatment were reinoculated in the eye (either in the cornea or in the anterior chamber). In one series the rabbits were simultaneously reinoculated in the skin of the shaved back. At the time the immune test rabbits were reinoculated, an equal number of normal rabbits were similarly inoculated as controls.

Altogether 43 presumably immune rabbits were tested in these three experiments. In 27 of them, or 62 percent, syphilitic keratitis developed after reinoculation in the eye, whereas it developed in 39 or 91 percent of the 43 normal control animals. It is clear from these results that whereas the eye does share in the immunity that develops during the course of a syphilitic infection, it does not do so to the same extent as do other tissues (skin, testis). This state of affairs was clearly brought out in one of the experiments in which both the cornea and the skin of the immune animals were reinoculated at the same time with the same virus. In this experiment the skin

proved to be completely refractory in every instance, whereas in 9 of the 14 animals the cornea was found to be susceptible to a second inoculation.

The first question can therefore be answered as follows: The cornea of a syphilitic rabbit sometimes participates in the general resistance to reinfection that develops in the other body tissues as a result of the syphilitic infection, but in the majority of instances, in our experience, it does not.

II. The second question—(a) Does a primary syphilitic infection in the cornea give rise to a general systemic infection? and (b) Does it impart to the other tissues of the body the same resistance to reinfection that develops when the primary focus is located in other tissues?—was investigated in two experiments.

It was found first of all that syphilitic virus does not remain localized in the cornea after intracorneal inoculation but that the treponemes regularly make their way into the circulating blood and can be recovered from distant lymph nodes in practically every instance. In this respect the situation is identical with that which obtains after intratesticular or intracutaneous inoculation. Secondly, it was found that a high proportion of the animals inoculated intracorneally—19 in 33, or 56 percent—became completely refractory to a second inoculation with syphilitic virus introduced into the skin. Of the remaining 14 animals, 8 showed a partial skin immunity and only 6 failed to show any evidence of immunity at all.

The answer to the second question, then, is as follows: (a) Primary syphilitic disease of the eye in the rabbit is followed by systemic syphilitic infection. (b) It is also followed, in the majority of instances, by the development in the skin of a considerable degree of resistance toward reinfection with the homologous virus but not so frequently as after intratesticular or intracutaneous inoculation.

The reason for this failure of skin immunity to develop in all animals after intracorneal inoculation is not clear.

III. The third question—Does a local syphilitic infection of the cornea produce a local immunity of the cornea to reinfection?—was explored as follows: Rabbits were inoculated in the cornea with syphilitic virus, the ensuing keratitis was allowed to run its course, and after a proper interval had elapsed for the animals to develop the usual immunity to reinfection they were treated with arsphenamine. After the completion of the arsphenamine treatment, the rabbits were reinoculated in the same cornea with the homologous syphilitic virus. The period between the primary and the secondary inoculation in these animals was approximately one year. The corneal vascularization incidental to the primary inoculation had largely undergone atresia in this period.

The results were as follows: Of 33 test animals, 25, or 76 percent, were found to be completely refractory to the second inoculation of the same cornea with homologous syphilitic virus, whereas 8, or 24 percent, developed a delayed second attack of interstitial keratitis, the average incubation period in the 8 reacting rabbits being 109 days against an average incubation period of 37 days in the controls. Thus, a high proportion of the rabbits showed a completely refractory state in the same cornea one year after the primary inoculation. The long incubation period in the eight rabbits which finally reacted may be evidence of either a partial or a fading immunity.

IV. An answer to the fourth and final question—Is the avascularity of the cornea responsible for the failure of that structure to become immune during the course of a syphilitic infection produced by inoculation elsewhere than in the cornea?—was sought in the following manner: Syphilitic rabbits inoculated origi-

nally in the testis were treated with arsenamine at a time when they would presumably have acquired an immunity against a second infection with homologous syphilitic virus. One cornea of each of these immune rabbits was then injected with an emulsion of killed tubercle bacilli in order to produce a nonspecific keratitis. The lesion was usually interstitial in type but occasionally ulcerative. In every instance it gave rise to a heavy vascularization of the cornea, from both the deep and the superficial loops of the blood vessels. After the acute inflammation had subsided and any ulcers present had healed, but before the vascularization had completely regressed, both corneas of these animals—that is, the artificially vascularized and the normal corneas—were inoculated with homologous syphilitic virus. These corneal inoculations were made 35 and 47 days after the injection of the tubercle bacilli. As controls, normal rabbits with similarly vascularized corneas were inoculated at the same time with the same batch of virus.

The experiment was carried out twice, and the results were essentially the same in each experiment. In every instance the artificially vascularized eyes of the immune rabbits were completely refractory to reinoculation. The result was not entirely conclusive because the group of test rabbits showed a high degree of immunity in the nonvascularized eyes. However, the experiments did indicate that rendering the corneas of syphilis-immune rabbits vascular by producing in them a nonspecific inflammatory reaction tends to make the corneas more refractory to a second syphilitic infection. This tendency may be due to an increased exposure to circulating syphilitic antibody brought about by the artificial vascularity of the cornea.

The answer to the fourth question therefore appears to be that the avascu-

larity of the cornea is a factor in the failure of the cornea to become immune during the course of a systemic syphilitic infection, and that vascularization of the cornea influences favorably the development of local resistance.

DISCUSSION

The experiments summarized in this paper indicate, in brief, that: (a) the cornea does not always share in the immunity to reinfection which develops during the course of an experimental syphilitic infection in rabbits; (b) direct inoculation of the cornea with treponemes is followed by the development in that tissue of a local resistant state toward those organisms, although in some cases the protection thus conferred is either not absolute or not permanent; and (c) vascularization of the cornea appears to be a factor in influencing favorably the development of a local resistant state.

Do these findings throw any light upon the pathogenesis of interstitial keratitis, or offer an explanation for the well-known facts: (a) that this condition is a comparatively late manifestation of congenital syphilis and is rarely found in the acquired form of the disease? (b) that it is usually refractory to the conventional forms of antisiphilitic treatment? and (c) that it has a marked tendency to recur?

Several different theories have been advanced to explain the pathogenesis of interstitial keratitis. Chief among them are (a) the trophic-disturbance theory, (b) the traumatic theory, (c) the allergic theory, and (d) the vitamin-deficiency theory.

The trophic-disturbance theory would explain interstitial keratitis on the basis of a presumed local nutritional deficiency due to blocking by syphilitic inflammatory tissue of the long ciliary arteries and perivascular lymphatics in the region of

the limbus (Wagenmann 1890,¹¹ van Michel 1881,¹² Loewenstein 1927¹³ and 1929¹⁴). It presupposes the presence of treponemes in the inflammatory process.

The traumatic theory, as the name implies, takes the ground that trauma—such as rubbing of the eyes, eye strain, foreign bodies, and infections—is the precipitating agent (Spicer,¹⁵ Butler,¹⁶ Klauder,¹⁷ and others). Here, again, the actual presence of treponemes in the cornea is postulated.

The allergic theory holds that interstitial keratitis represents an allergic reaction in the cornea due to a sensitization of that tissue in fetal or early life by the syphilitic virus, and intoxication of it in later life by the treponemes or their products (Igersheimer,¹⁸ Derby and Walker¹⁹). This theory presupposes that either the treponemes or their products invade the cornea a second time.

The vitamin-deficiency theory, as the name indicates, holds that the lesions are due to a lack of certain vitamins, particularly riboflavin (Kruse, *et al.*)²⁰

No one of these mechanisms may be said to have been established as the cause of interstitial keratitis. Three of the four theories, however, require the presence of treponemes or their products in or about the corneal lesion.

The fact that treponemes have been found in the corneas of patients with active interstitial keratitis (Igersheimer,¹⁸ Clausen,²¹ Weve²²), and are also present in the corneas of syphilitic rabbits that show a metastatic keratitis, strongly suggests that the lesion of interstitial keratitis is an inflammatory process due to the presence in the cornea of the treponemes themselves, and makes it unnecessary to assume a nutritional deficiency due to a disturbance of circulation, or a lack of any vitamin, or an allergic process precipitated by treponemal products, in order to explain the occurrence of the lesion.

If the lesions of interstitial keratitis do not represent allergic phenomena or nutritional deficiency, but are simply inflammatory reactions occasioned by the local invasion and growth of treponemes, they are then part and parcel of an infectious process. On this basis the factors of local invasion and specific immunity, engendered by the infection itself and representing the host's local or general reaction to the invading organisms, each play a role in the pathogenesis of the lesions, and may also be responsible for any peculiarities which they exhibit. Therefore it is logical to examine the factors of local tissue invasion and specific immunity in relation to the cornea, from the standpoint of what is generally known about syphilitic infection and from the standpoint of our own experiments as well.

As concerns the question of local invasion, the precise extent to which treponemes lodge in the corneas of congenitally syphilitic children both before and after birth is, of course, not known. There is certainly, however, a wide dissemination of the organisms throughout the body in the early stages of both congenital and acquired syphilis, and there is evidence that some of the treponemes do reach the eye in congenital syphilis during the period of dissemination. Histologic examinations of the eyes of syphilitic fetuses and of stillborn syphilitic infants have shown, first, that a large percentage of such eyes show minor syphilitic lesions throughout the iris and choroid (Yoshida,²³ Rumbaur,²⁴ Friedenwald²⁵), and second, that treponemes are widely disseminated throughout the uveal tract (Bab,²⁶ Waetzold²⁷). Treponemes have also been demonstrated in the corneas of such eyes (Stock,²⁸ Bab,²⁶ Waetzold,²⁷ Schlimpert,²⁹ and von Hippel³⁰), although probably not in as great numbers as in the uveal tract. However, clinically recognizable lesions are extreme-

ly rare either in the cornea or iris in the early stages of congenital syphilis. Why do the treponemes which lodge in the eye not produce clinically recognizable lesions? Is it because (a) the human cornea, whether young or adult, does not constitute a favorable site for the multiplication of treponemes? or (b) is it because the cornea acquires fairly early a specific immunity, engendered, perhaps, by syphilitic lesions elsewhere?

In regard to the first of these possibilities it may be pointed out that not all tissues of the body offer favorable sites for the growth of treponemes and the development of syphilitic lesions. Thus it has been shown that treponemes can be recovered from the spinal fluid of patients with early syphilis in a fair (15 to 20 percent) proportion of the cases although there is no clinical evidence of neuraxis involvement in them, and the spinal fluid itself shows no abnormalities. In spite of this apparently frequent invasion of the human central nervous system by treponemes early in the course of acquired syphilis, the incidence of actual syphilitic disease of that system is much less than the incidence of invasion. It is possible that the cornea of infants may also be an unfavorable environment for the development of syphilitic lesions. Whatever may be the situation with the very young human cornea, the rabbit's cornea is a favorable site for the growth of treponemes, for keratitis is one of the commonest of metastatic lesions following intratesticular inoculation of that animal with syphilitic virus, and direct inoculation of the cornea also produces lesions in the majority of instances.

In regard to the second possibility—namely, that the cornea may acquire a specific immunity fairly early in the course of syphilitic infection—it may be recalled that Brown and Pearce²¹ noted

that lesions of the eyes were the last of the metastatic lesions to occur in experimental syphilis in rabbits, and usually developed in animals that had not had generalized lesions of other tissues (skin, bones). They thought that the occurrence of lesions elsewhere in the body protected the eyes from the development of syphilitic lesions in those organs. According to their view, the reactions of other tissues to the syphilitic virus can confer, or help to confer, upon the rabbit's cornea a specific resistance to syphilitic infection, and it may be presumed that if the reactions in other tissues are less marked or absent, then the resistance imparted to the cornea is correspondingly less or may be completely lacking. As a result of this diminution or absence of immunity, lesions might well develop in the cornea. Our own experiments have shown that while the cornea sometimes shares in the immune process it does not regularly do so under the conditions of our experiments. However, in those experiments the corneal tissue was subjected to a very severe test for immunity. Large doses of highly virulent treponemes were injected in the supposedly immune animals, and it is possible that more evidence of immunity would have been obtained had the test inoculum been smaller.

It seems reasonable to suppose that the comparative absence of lesions of interstitial keratitis in the early years of congenital syphilis, and also during the course of acquired syphilis, may be based upon the presence of acquired resistance in the cornea sufficient to prevent the growth of treponemes in that tissue. Can this conception, which is essentially immunologic in character, be invoked to explain the fact that interstitial keratitis is almost always a late lesion of congenital syphilis, occurring very rarely in the first years of life and most frequently between the ages

of 8 and 15, the peak of incidence being reached in the eleventh year? The answer is that such an immunologic conception will explain the late incidence of the disease if we assume that the immunity which the cornea acquires is not necessarily permanent but may subside with time. This is a reasonable assumption and is in accord with our own experiments. If the corneal immunity does subside and a syphilitic lesion develops in the cornea then the question arises whether the treponemes causing the lesion have been lying dormant in that tissue for years or have lodged there recently during the course of a fresh dissemination by the blood stream. Nothing is known as to how long treponemes may remain viable but dormant in the cornea, or whether or not a new dissemination of those organisms occurs late in the course of congenital syphilis. In any event, if the occurrence of the keratitis of congenital syphilis is to be explained upon an immunologic basis, we must conclude that when the lesions develop the affected cornea has lost whatever immunity it may ever have possessed. And we must conclude also, on this basis, that any immunity which the adult human cornea acquires during the course of acquired syphilis is long lasting and of high degree, for it is well known that interstitial keratitis is a very rare manifestation of acquired syphilis.

The unknown factors in the situation, which make it difficult to round out the immunologic theory of the pathogenesis of interstitial keratitis, are the amount of time which is required for the development of corneal immunity in the syphilitic fetus or infant, and the extent of the syphilitic process, either in the cornea itself or in the other tissues, which is necessary to render the cornea immune. Our experiments have shown that some syphilitic rabbits acquire a corneal immunity to

syphilis within at least 163 days after the original inoculation and they may well acquire it even earlier, if one may judge by the time required for immunity to develop in the skin or testis. It is easily conceivable that the congenitally syphilitic infant may have had his syphilis *in utero* long enough to have acquired a corneal immunity. Moreover, it is possible that the subclinical lesions which have been found in the eyes of syphilitic fetuses and of stillborn syphilitic children may produce a sufficient degree of local immunity in the cornea to protect that tissue against the development of lesions for some time, even if the immunity is not great enough to kill off all of the treponemes causing the reaction. Our experiments have shown clearly that the cornea itself can become immune to syphilis after it is inoculated with treponemes and a lesion develops, even though other tissues in the same animal, such as the skin, may not become immune following a primary corneal inoculation.

The results of our experiments, therefore, together with what is now known concerning the local invasion of the treponemes in syphilis and the development of specific resistance against them, are entirely compatible with the conception that the interstitial keratitis of congenital syphilis is due to the actual presence of treponemes in the cornea plus a subsidence or lack of specific resistance in that tissue to the organisms. This may not be the entire story, however, for it is conceivable that trauma may also play a role in the development of the condition, as many ophthalmologists have urged.

The specific traumatic incidents which have been suggested as playing a role in the pathogenesis of interstitial keratitis are the continual rubbing of the eyes, with resultant hyperemia and conjunctivitis; the constant irritation associated

with eyestrain; the presence of foreign bodies; and minor infections. All of these common conditions will produce a superficial nonspecific inflammatory reaction of varying intensity which is frequent or constant in older children and not present usually in infants. Butler reported a history of preceding trauma in 20 percent of his studied cases. Whether the common traumatic incidents just referred to are sufficient to initiate the syphilitic process in the cornea cannot be stated categorically, but the association of syphilitic lesions, especially of the late gummatous variety, with trauma has long been known. Moreover, it has been demonstrated experimentally that a nonspecific inflammatory process resulting from trauma offers a favorable environment for the growth of syphilitic virus and the development of syphilitic lesions.³² In the experiments which we are reporting here in summary form, a nonspecific inflammatory reaction in the normal cornea, produced artificially, was found definitely to hasten and enhance the development of a syphilitic lesion in that tissue after the direct inoculation of syphilitic virus.

The manner in which trauma influences favorably the development of a syphilitic lesion is not clear, although it is probably directly related to the inflammatory reaction that is set at the site of the injury rather than to the injury itself. One of us (A. M. C.) has already suggested that the effect of the inflammatory reaction is to establish conditions which are favorable for the growth of the cells of the body and that these conditions also favor the growth of the treponemes.

Trauma, therefore, cannot be ruled out as a possible contributory factor in the causation of interstitial keratitis. However, when we hypothecate trauma as a possible precipitating factor, we do so with certain reservations. Our experiments

have indicated that in the syphilis-immune animal, trauma sufficiently severe to produce vascularization of the cornea does not enhance the liability of that structure to the development of syphilitic lesions but, on the contrary, renders it resistant to reinoculation with treponemes. Therefore, when we hypothecate trauma as a possible factor which would dispose the eye of a congenitally syphilitic child to the development of interstitial keratitis, we must assume that such trauma would be minor, resulting in congestion of the conjunctival and limbal vessels with secondary cellular changes, and be insufficient to produce corneal vascularization. This assumption appears to be in accord with the general clinical experience. On this basis—minor trauma plus a diminished local resistance—interstitial keratitis, and indeed many of the other lesions of late syphilis, can be explained.

In a chronic infection such as syphilis the development of a late lesion *ipso facto* indicates the inadequacy of the resistant state at the site where the lesion develops. If we follow the general assumption that in syphilis, as in other chronic infections, there develops a delicate balance between the host and the invading agent, so that the organism is not killed off altogether but remains alive in certain tissues, though dormant, then it is easy to imagine that this delicate equilibrium might be upset by (1) the subsidence of the host's specific resistance, or (2) by the development, through trauma or some other as yet unknown factor, of conditions which favor the growth of the treponemes *in situ*, or (3) by a combination of both factors. The result would be the tipping of the scales in favor of the invader with the development of lesions. This conception seems to us to offer the most satisfactory explanation for the occurrence of interstitial keratitis.

In relation to this immunologic theory, a word should be said about the allergic theory. It is true that the late gummatous lesions of syphilis are usually thought to be allergic in character. This view is based upon the extreme scarcity of treponemes in gummata, although the tissue reaction in such lesions is very extensive. To explain these facts it is supposed that the infected individual has become allergic, so that he reacts with a maximal response to a minimal stimulus. The lesions of interstitial keratitis may be allergic in origin, but it would be extremely difficult to prove the point. There are no reliable agents at the present time for testing human beings for allergy to syphilis. Moreover, nobody has ever made any animal allergic to treponemes or their products by any procedure whatsoever. We attempted to render the corneas of normal rabbits allergic to an emulsion of syphilitic-rabbit's testis containing large numbers of treponemes but failed completely to do so. In addition, there was no evidence that the corneas of the syphilis-immune rabbits were at all allergic to syphilitic virus inoculated in large amounts. There is, therefore, no direct supporting evidence for the view that interstitial keratitis is an allergic phenomenon.

There remains the question whether the two other particular characteristics of interstitial keratitis—namely, its refractoriness to treatment and its tendency to recur—can be explained upon the basis of the factors which we have been considering. It is well known that interstitial keratitis is refractory to the conventional forms of antisyphilitic treatment. This may be due in part to a relatively low concentration of arsphenamine in the avascular cornea as compared to other more vascular tissues, for recent experiences with penicillin indicate that when

that agent is brought to the cornea in high concentration by such a local procedure as iontophoresis, healing of the lesions of interstitial keratitis takes place rapidly and is accomplished without vascularization. However, it has long been recognized that as soon as vascularization of the cornea is well established or complete in cases of interstitial keratitis, rapid clearing of the infiltrate and subsidence of the inflammation ensues.

This occurs irrespective of the kind of treatment, and indeed without any treatment at all. In short, vascularization of the cornea *per se* makes that tissue an unfavorable environment for the continuation of a syphilitic lesion. Our experiments indicate that vascularization of the cornea in a syphilitic rabbit favors the development of a local resistant state in that tissue, and it seems more than probable that the development of such a local immunity, presumably through antibodies coming from the blood, is the reason for the prompt healing of the keratitis that takes place once vascularization is established in the congenitally syphilitic cornea, since healing may ensue in the absence of antisyphilitic agents, but not usually in the absence of vascularization. Failure of interstitial keratitis to yield promptly to antisyphilitic treatment, then, may be due primarily to lack of vascularity and concomitant low concentration of the treponemicidal drug, and healing of the lesion in the absence of antisyphilitic drugs may be due to an increase in specific local resistance produced by vascularization.

The tendency of interstitial keratitis to recur is well known. Numerous studies of the effect of antisyphilitic treatment upon this condition indicate that in untreated or partially treated cases the incidence of recurrence may be as high as 27 percent, whereas in well treated cases

it may be as low as 2 percent. If the assumption that the healing of the lesions of keratitis is due largely or in part to the development of a local immunity coincident with vascularization of the cornea is correct, then, in order to explain the high incidence of recurrences in inadequately treated cases where the treponemes have obviously not been destroyed, it is necessary to assume that the local immunity is transitory and not permanent. Such a diminishing local immunity, plus the ever-present factor of minor trauma, would readily account for the high incidence of local recurrence in untreated cases.

Our experiments give no convincing data upon the duration of local immunity, once it is established. The data we can offer in this connection are scarcely suggestive. Of 33 rabbits which were inoculated originally in the cornea and in which the syphilitic lesions became vascularized and healed prior to treatment with arsphenamine, 25, or 76 percent, were totally immune to a second inoculation with the homologous strain of treponemes carried out about a year after the onset of vascularization. The remaining eight reacted with lesions in the cornea but after a very long incubation period. These eight may have had only a partial immunity in the beginning which faded somewhat with time. It would require repeated corneal reinoculations in syphilitic rabbits to establish the point.

SUMMARY

A series of experiments is reported in summary, which indicates that: (a) the corneas of rabbits with experimental syphilis induced by intratesticular inoculation do not always share in the immunity to reinfection which develops during the course of the syphilitic infection; (b) direct inoculation of the cornea is followed by the development, in that tissue, of a local resistant state toward those organisms, although in some instances the protection thus conferred is either not absolute or is not permanent; (c) vascularization of the cornea appears to be a factor in influencing favorably the development of a local resistant state.

The bearing of these findings upon the pathogenesis of interstitial keratitis and upon other phenomena associated with this condition is discussed. It is suggested that the usual late occurrence of the lesions of interstitial keratitis may be due to a combination of lack of local immunity in the cornea in some cases of congenital syphilis, plus the occurrence of minor traumatic incidents as the initiating factor. The fact that the lesions of interstitial keratitis will heal spontaneously when vascularization occurs may be explained upon the basis of the development of a local immunity, presumably through antibodies coming from the blood. The tendency of the lesions of interstitial keratitis to recur may be related to the fading of a local immunity.

ATOPIC CATARACTS*

REPORT OF FOUR CASES

FREDERICK C. CORDES, M.D., AND RAFAEL CORDERO-MORENO, M.D.
San Francisco, California

That there is a definite relationship between various types of dermatitis and cataract formation has been recognized for some time. In 1868 Rothmund¹ reported on the association of juvenile cataract with an unusual type of dermatosis. The condition did not appear in the American literature, however, until 1921, when Davis² reported the case of a girl, aged 15 years, with neurodermatitis, who developed cataracts that matured in one year. Since that time an increasing number have been reported. Daniel³ reported three cases in 1935, Brunsting⁴ 10 cases, including Daniel's cases, Beetham⁵ 10 cases in 1940, and McDannald⁶ two cases in 1943. Bellows⁷ in 1944 stated that up to that time over 40 cases had been reported in the literature and added that undoubtedly many more cases have been observed since the condition is readily recognized by ophthalmologists.

Cataracts associated with dermatosis come under three main classifications: 1. neurodermatitis (Andogsky syndrome); 2. poikiloderma atrophicum vasculare (Rothmund's disease, Jacobi's disease); 3. scleroderma (Werner's disease). In addition Buschke⁸ points out that cataracts have been associated with keratosis follicularis (Darier's disease), telangiectasis, myxedema, and certain anomalies of the hair (curly hair; alopecia, and aplasia pilaris). Here we are concerned only with the cataract seen in association with neurodermatitis.

Neurodermatitis is characterized by

pruritus associated with lichenification and shows a typical distribution. It may be either exudative or dry. This latter type, in which cataract formation is seen, has been designated by Coca⁹ as *atopic dermatitis* and has resulted in these cataracts being called *atopic cataracts* in the American literature. Coca has classified allergic diseases under the following headings: (1) atopy (hay fever, asthma, and eczema), (2) contact dermatitis, (3) serum allergy, and (4) drug allergy.

Löwenstein¹⁰ and others have attempted to show that these cataracts are endocrine in origin, most likely on a basis of thyroid deficiency. Laboratory and clinical observation have, however, been disappointing. The name neurodermatitis has been applied because of the fact that these patients frequently have disturbances of the autonomic nervous system, together with the presence of nervous instability and exhaustion. Psychiatric maladjustment is also frequently present. As Bellows⁷ points out, the intense discomfort of neurodermatitis might explain the nervous instability. While there is still a good deal of discussion as to the cause of the dermatitis and the causative factors must still be considered unsettled, the tendency in this country is to accept the allergic theory, and the term atopic dermatitis.

Atopy is defined as the condition of being sensitive to an allergen. Coca⁹ has used the word atopy to express the unusual hereditary tendency of some individuals to develop severe reactions to certain common protein materials, the reaction being accompanied by hay fever, asthma, and eczema. Thus atopy implies

* From the Division of Ophthalmology, University of California Medical School.

the presence "in the serum of the circulating blood of atopens or reagins, known as Prausnitz-Küstner bodies."⁵ These reagins can be passively transferred to the normal skin of another individual, who will react to the specific antigen (Prausnitz-Küstner test).

According to Coca⁹ atopic dermatitis can be differentiated from other allergic manifestations of the skin by the following characteristics: (1) its familial tendency, (2) the allergins are antigens, (3) the formation of reagins (antibodies), (4) the skin test.

Sulzberger and Hill¹¹ are of the opinion that the atopic stigma is acquired during the embryonic life of the individual, by means of the passage of certain proteins through the intestinal digestion to the mother's blood and hence to the embryo without undergoing any alteration and provoking in the latter a specific reaginic reaction. The sensitivity continues through childhood and persists into adult life, tending to disappear in middle life.

During infancy the eczema is of the weeping, crusty type. During childhood a papular eruption is present, which may or may not be accompanied by asthma. In adult life the lesions consist of elevated papules and dry, scaly, lichenified plaques. These lesions may become secondarily infected, with oozing, weeping, and crust formation. The lesions, which are accompanied by intense pruritis, have a predilection for the antecubital and popliteal fossas, side of the neck, face, and forehead. At times there may be generalized involvement.

The course of the disease is chronic, with intervals of months or years between severe exacerbations. The condition is worse in cold weather. In some cases, as in our fourth case, a change of climate may be very beneficial.

Cataract formation as part of the pic-

ture in neurodermatitis was first described by Andogsky.¹² What is usually considered a typical form of atopic cataract is the formation of a white milky plaque in the pupillary area which may be localized in the region of either the anterior or posterior pole of the lens, involving the superficial layers of the lens cortex. Benedict¹³ observed that the early changes are granular deposits in the anterior capsule and an increase in prominence of the Y suture lines. The mature cataract appears gray or light cream in color. Beetham⁵ states that two types of cataract can be described, the first being the typical and commonly seen complicated cataract which begins at the posterior pole with increased iridescence, vacuoles, and precipitates. Striation of the lens fibers is often present as are small punctate opacities and iridescent crystals. These changes spread rapidly, involving the anterior cortex immediately beneath the lens capsule. The opacities then progress to a homogeneous mature cataract, the picture being that of the usual complicated cataract. The second type consists of a dense, irregular, opaque plaque in the pupillary area just beneath the anterior lens capsule. The capsule may be wrinkled or irregular but is essentially normal. Vogt¹⁴ refers to this type as the neurodermatitis cataract. Thirty to 50 percent are unilateral.

The incidence of cataract in atopic patients is unknown. The 10-percent incidence found by Brunsting⁴ in his series would indicate the possibility of a rather high occurrence. It would be interesting to conduct a survey of atopic patients to determine whether or not cataract formation is present in those who show no evidence of dermatitis. If cataracts were present only in the group that showed evidence of dermatitis, one would favor the theory that the lens opacities are the local manifestations of an ectodermal af-

fection. If present in atopics without dermatitis the condition would then be considered as part of a more generalized process.

The age at which the cataract makes its appearance is variable, with the highest incidence in puberty and young adult life. The patient reported by Davis² was 15 years old. Brunsting's⁴ series shows an average of 22 years, the youngest being 13 and the oldest 35. The average in Beecham's⁵ series was 22. McDannald's⁶ patients were 18 and 22 years old. Our patients were 18, 32, 49, and 21 years old. Our 49-year-old patient is the oldest to be reported. The previously oldest case to be reported was Olmann's¹⁵ 46-year-old man.

Sex has no apparent influence in the incidence of cataract in atopic dermatitis.

The mechanism of the formation of the lens opacities is uncertain. The theory that the lens opacities are the manifestation in the lens of an ectodermal disease is the most fascinating. This theory is supported by the fact that other dermatoses such as scleroderma and poikiloderma atrophicum may be accompanied by cataract formation. This theory, however, excludes the possibility of cataracts in atopics without dermatitis. On the other hand, as Vaughan¹⁶ has pointed out, each allergic patient has organs or tissues wherein his allergy is manifested which are called "shock organs" or "shock tissues." Such organs may or may not change with time and the allergens. Coca¹⁷ speaks of "atopic shock organs." He feels that the lesions of atopic hypersensitiveness are encountered in many parts of the body, and when they occur in special organs he refers to them as "shock organs." Thus the skin, conjunctiva, nasal mucous membrane, bronchi, gastrointestinal tract are recognized shock organs, and to these may be added perhaps the urinary bladder and the ret-

ina. Coca¹⁸ reports retinal edema associated with food allergy. Balyeat¹⁹ reported bilateral complete retinal detachment in a young woman of 21 years, who had an atopic dermatitis. She developed eczema at 3 months of age followed by asthma and hay fever when she was 12 months old. While the asthma gradually became less severe, the eczema slowly increased until at 16 years the eruption was marked about the face and chest. The patient first noted the visual disturbance when 17 years of age, when retinal detachment was diagnosed for the first time. The patient was found to be sensitive to a number of foods and inhalants. This report is of particular interest because of the retinal detachment in case 4 reported here.

With this conception one can easily understand how the lens, at times, may be the atopic shock organ and that any atopic patient, with or without dermatitis, may have lenticular opacities. The influence of vitamins and endocrine secretions is not clear in these cases. The part played by the nervous system cannot be evaluated, owing to the fact that it is difficult to determine whether the nervous upset is an etiologic factor or a consequence of the atopy. Alan Woods²⁰ believes that the lens capsule in these cases is damaged, permitting normal aqueous to enter the lens, thus producing an ordinary traumatic cataract.

The treatment of these cases is surgical. No difficulties are encountered, although Brunsting⁴ warns that, because of the tendency of the capsule to rupture, intracapsular extraction is more difficult. However, almost all of these patients fall in an age group wherein intracapsular extraction is not generally accepted as an advisable procedure. Bellows⁷ also states that because of the fact that sclerosis of the lens occurs early in these cases lineal extraction is frequently contraindicated.

REPORT OF CASES

Case 1. M. M. J., a white male, 15 years old, was seen in the outpatient department on October 20, 1944, complaining of loss of vision.

The father had had asthma for many years and one brother has hay fever. The patient's birth was normal. Between 6 months of age and 3½ years he had infantile eczema. At seven years he had asthmatic attacks that persisted for a short time. He was then free from symptoms until the age of 10, when he again developed attacks of asthma. One and a half years before entry he had a severe attack of asthma following a football game in which he participated. The next morning he noted red, moist, pruritic skin lesions on his face, arms, trunk, and legs that have persisted since that time.

Physical examination. Keloid scars were observed on the back and back of the legs as a result of burns as a child. The skin of the face and trunk as well as of the arms and legs showed a dermatitis with crusting and lichenification. There was eczema of the external auditory canal.

Ocular examination. Right Eye: External examination was negative. Slitlamp examination showed fine anterior subcapsular opacities with larger posterior subcapsular opacities with "cloth of gold" reflex. Both Y's were somewhat prominent. Vision 20/30—1, unimproved by lenses. The fundus was negative.

Left Eye: External examination was negative. The slitlamp disclosed very few fine anterior subcapsular opacities, with rather marked posterior opacification (subcapsular). Both Y's were prominent. The fundus was negative.

Nasal smear showed eosinophiles + + +. The blood count showed on eosinophilia of 11 percent.

Allergy tests. The patient proved to be allergic to pollens of various trees and

to some spring plants, but not to foods.

Case 2. G. M., a white man, 32 years old, reported to the outpatient department on December 4, 1944, because of progressive loss of vision.

No familial history of allergy was obtained. The patient had eczema at five years of age that cleared after a short time. He had no further difficulty until 1933, when he developed an eczema of the face, arms, and elbows that was severe for a time and then disappeared, only to reappear later. The intervals between attacks were a few days to a few months. He had received treatment for his atopic dermatitis in many parts of the country. In June of 1943 he noted blurred vision in his right eye, followed a little later with difficulty with his left eye.

Physical examination. The patient failed to return for general physical examination so that aside from the typical atopic dermatitis no data are available.

Ocular examination. Right Eye: The external examination was negative; the slitlamp showed rather well-advanced anterior and posterior subcapsular opacities. The fundus was grossly negative.

Left Eye: The external examination was negative; the slitlamp showed anterior and posterior subcapsular opacities similar to those seen in the right eye.

Case 3. L. L., a 49-year-old Chinese male, reported to the outpatient department on January 9, 1945, complaining of diminution of vision in his right eye, with right monocular diplopia.

A son and a daughter have rather severe hay fever. The patient has had severe itching of the face and hands since 1943, and has a generalized atopic dermatitis with induration, crusting, and lichenification. Leprosy was suspected, but a biopsy specimen was negative.

Physical examination. Aside from the

atopic dermatitis this was negative.

Ocular examination. Right Eye: Vision 20/70 was unimproved by lenses. Slit-lamp examination showed somewhat dense central posterior subcapsular cataract. Aside from this the examination was negative.

Left Eye: Vision was 20/30. External examination was negative. The slitlamp showed some diffuse fine dotlike white opacities throughout the lens. The fundus was negative.

Allergy tests revealed sensitivity to a number of pollens. The treatment prescribed on this basis has helped his general condition a good deal.

Case 4. (Most of the data in this case were kindly provided by Dr. L. L. Henry, of Pasadena, who has been watching the case.)

E. T., a white girl aged 17 years, was first seen on November 20, 1944, complaining of marked itching, tearing, and burning of the eyes after reading.

She had had a mild eczema of the face, wrists, and elbows since the age of three years. There was a history of asthma and hay fever. Tests showed an allergy to chocolate, fowl, and rabbit. Childhood illnesses, except for the allergies, were not unusual or significant. The patient was severely constipated and was using mineral oil and N-R tablets for relief of this. Menstrual history was negative. The genito-urinary system was negative except for an irritating leucorrhea. The heart and lung history was negative except for the asthma and three mild attacks of pneumonia.

Eye examination at this time was entirely negative except for a mild allergic conjunctivitis.

The patient was then sent to Arizona for two years where, according to her statement, she was entirely free from symptoms. As soon as she returned home her symptoms returned and she became

so ill that she was sent to a sanitarium.

When the patient was seen on April 19, 1944, the vision of the right eye was reduced to perception of fingers at one foot in the lower field; vision of the left eye was 20/100, unimproved by glasses. The patient stated that her vision had been failing during the last month. The dermatitis had been much worse, and she had been rubbing her eyes and slapping her face to allay the itching.

Examination at that time revealed a retinal detachment in the right eye in the superior and temporal quadrants, including the macula. The vitreous was cloudy. The left eye showed a definite edema of the entire retina. It was thought at this time that the detachment was due to allergy and edema and that it was similar to the detachment seen in pregnancy. The consultant at the time was of the opinion that the process was self-limited and that the retina would become reattached as the edema subsided.

Two months later, on June 20, 1944, examination revealed the retina in the right eye to be almost completely detached, except for a small area in the superior nasal quadrant. The vitreous was cloudy; the lens clear. The left eye still showed edema. The patient's general condition was such that operation could not be considered. On July 19, 1944, the right eye presented a dense cortical cataract. Only questionable light perception was present. In the left eye, at this time, the posterior cortical area showed early opacities; there were numerous fine vitreous opacities. The retina was more edematous.

The patient was last seen on November 27, 1944. She still had the typical atopic dermatitis. The cataract in the right eye was practically mature. The eye was amaurotic. The left eye had vision of 20/100, unimproved by glasses. Examination revealed a fairly dense posterior capsular cataract. The retina, seen with difficulty, was apparently still edematous. The

field was normal to large test objects. Tension was 20½ mm. Hg (Schiotz).

COMMENTS

Four cases of cataract formation in patients with atopic dermatitis are reported.

Two of the cases warrant special comment. In case 3 the skin condition had been diagnosed as possible leprosy until a biopsy specimen proved otherwise.

In case 4 there was the additional complication of retinal detachment in one eye with edema of the retina and a definite edema of the retina in the other eye. With a history of allergy, and an allergic conjunctivitis, it seems justifiable to attribute the edema and the detachment to allergy. The rubbing of the eyes and slapping of the face to allay the itching

may have been an additional factor in producing the detachment. This case we feel can be considered as adding evidence in favor of the allergy theory, particularly in view of Coca's report of retinal edema on an allergic basis and the case of bilateral retinal detachment associated with allergy, reported by Balyeat.

A brief résumé of the allergy theory has been given, in particular the theory of Coca, for which he coined the phrase atopy, because it would seem that cataract formation must be considered as an uncommon part of the syndrome. The theory of the atopic shock organ seems admissible.

Detailed ocular examination in all cases of atopic dermatitis seems to be warranted.

THE SURGICAL TREATMENT OF STRABISMUS*

DANIEL B. KIRBY, M.D.

New York

Monocular vision with its attributes may well serve the individuals who do not know the transcendent quality of stereoscopic binocular single vision with spontaneous appreciation of form, speed, direction, and distance, the highest attributes of human eyes. The principles of the orthoptic and surgical treatment necessary for the development or restoration of binocular single vision involve a study of monocular vision and accommodation, the correspondence of images of the two eyes, convergence, divergence, the transmission, reception, fusion, and interpretation of the images of the two eyes, and a consideration of the factors which interfere with them.

NECESSARY ORTHOPTIC AND SURGICAL TREATMENT

After the factors have been considered and the data assembled that conduce to the development of an individual case of strabismus, one is in a better position to evaluate the orthoptic and surgical measures that may be necessary to correct the condition. Orthoptic exercises are desirable and in most cases necessary before and after surgery. The observations made during repeated orthoptic analyses help much in determining the course to be pursued and the type of surgery that is suited to the case. The parents and particularly the patient

should be convinced that the desirable objective is not simply a cosmetic result but a functional one as well. Every effort should be made to develop or restore monocular vision in each eye separately and then to remove the obstacles which hinder correct binocular vision. Anomalous correspondence may prove more of a stumbling block than that of the restoration of central vision of the deviating eye through prolonged and continuous occlusion of the dominant eye. If the eyes are not finally made to see "eye to eye," the gains made by occlusion may be lost as soon as the dominant eye is uncovered. The errors of refraction and aniseikonia as well as other factors should be corrected so that when normal correspondence and sufficient vision is developed in the deviating eye, the act of binocular vision may be maintained. The eyes should be given every opportunity to develop desire, amplitude, and strength of fusion to resist factors that tend to break it up. Excursive exercises of each eye separately and of both together into the planes of movement or action of the extrinsic ocular muscles are helpful in relieving spasm or weakness and reestablishing normal individual muscle tone. The ophthalmologist should make the analysis and diagnosis with or without the aid of an orthoptic technician, and he should supervise the actual carrying out of the exercises by a person who has the time and patience necessary to achieve the result. The technician should understand the case so that he or she may intelligently coöperate. It is unwise, however, for the technician to assume or be given complete charge of the patient. The coördination of such effort of

* From the Department of Ophthalmology of the College of Medicine of New York University and Bellevue Hospital. The author is indebted to the writings and teachings of Berens, Duane, Dunnington, Jamison, Lancaster, Reese, Wheeler, and White. A condensed form of this article was published in Spanish in the proceedings of the Association para Evita de Ceguera in Mexico, 1945.

the ophthalmologist and the orthoptist is for the welfare of the patient.

PRINCIPLES OF SURGERY IN CASES OF STRABISMUS

After a period of orthoptic training, satisfaction may have been found in complete correction of the heterotropia by various nonsurgical means. If this is not accomplished, the aid of surgery may be necessary to realign the eyes so that training for, and establishment of, binocular single vision are possible. On general principles, weakness of a muscle or associated muscles may be relieved by resection, advancement, or tucking of one or more muscles at their insertions, whereas spasm or overaction of a muscle or associated muscles may be relieved by tenotomy, myotomy, recession, or retroplacement of the muscle or muscles at their insertions. The inferior oblique is the one exception. It may be approached either at its origin or at its insertion. In actual practice, if one or more of the horizontal muscles are parietic and there exists overaction of their associates, the solution is through a conservative surgical procedure on one or both muscles as indicated. The full plan of operation cannot always be satisfactorily made before the operation. The condition of the muscles when exposed to direct view may determine the exact course of the surgery. In cases of horizontal strabismus, both the lateral and medial rectus muscles should be exposed and observed before the operation on either one of them is completed. Usually, it is best to expose first the muscle which is weak, then the overacting muscle; the conditions are evaluated, and the operation of recession of the overacting muscle, if necessary, is completed before resection of the weaker muscle is performed. Certainly, one should not fol-

low a routine of using one operation for all types of convergent or divergent strabismus, but should individualize and particularize in each case and apply the procedure in the measure that is suitable, purposely never doing too much. The surgeon should be content with an undercorrection that may be amenable to a further procedure rather than to accomplish too much and then find it difficult to reconstruct. He should be willing to operate on the fellow eye, when it is necessary, rather than try to correct a great degree of strabismus by an extensive operation on one eye; even to operate on the dominant eye in cases of monocular fixation, when the surgery on the deviating eye proves insufficient.

THE DECISION TO OPERATE

The decision to operate is made only after (1) complete cycloplegia with refraction, (2) observation of the effect of the correction of ametropia, (3) comparison of subjective and objective tests of vision, tests for correspondence, degree of fusion, rotation, monocular and binocular uncover tests in the primary position and in the six cardinal points of gaze, (4) occlusion of the fixating eye and the correction of amblyopia, if possible, (5) excursive exercises with both eyes open and also with one eye occluded, (6) development of normal correspondence, if possible, (7) fusional training. If all of these preliminaries have been tried and strabismus still exists after a reasonable period of endeavor, or if the deviation is such that fusion is impossible without cumbersome devices that can be applied only for a brief period of time, then surgery is indicated to correct the cosmetic blemish and to give the patient a chance to develop useful binocular vision in the improved position of the eyes.

SURGERY NECESSARY FOR THE CORRECTION OF STRABISMUS MAY WELL BE PERFORMED AT AN EARLY AGE

The time of operation is not governed by an age limit. No advantage is gained by delaying the operation until a child has attained a certain age for fear that the eye will deviate again in either the same or the opposite direction, or in the mistaken notion that the eyes or the muscles are insufficiently developed to permit satisfactory surgery.

Strabismus is a definite handicap to the young patient in developing his personality and aptitudes. From a purely psychologic viewpoint, early surgery is indicated, certainly before the school age of four to six years has been reached, and the child subjected to the taunts and unkind remarks of playmates who take particular delight in being cruel in this respect. The possibility of functional development is greater if conditions are remedied early before the growth or developmental stage is passed. The vocations open to the young person and the manner in which he may achieve success in them are far better if he has good central vision with fusion and stereopsis than if he has only one good eye and must orient himself by the application of the phenomena of parallax.

THE CONSERVATIVE APPROACH TO THE SURGICAL CORRECTION OF STRABISMUS

As has been stated, it is better to perform a conservative operation which may require further surgery at a later date than to do too much or operate on too many muscles at one time. This practice has been successful and has prevented overcorrections that are difficult to relieve. The effect of too much surgery is hard to estimate. It is desirable also to allow a suitable length of time to elapse between operations so that the tissues

may resolve and heal completely, and the capacity of the muscles be demonstrated in their new positions before a second operation is determined upon.

THE SURGICAL ARMAMENTARIUM FOR CASES OF STRABISMUS

Various operations have been developed and described as applicable to the correction of strabismus. I shall describe procedures and techniques that I have found most satisfactory and reliable for achieving good results in the correction of ocular deviations.

Tenotomy—freely applied to the lateral rectus, but only in guarded form to the medial rectus.

Myotomy—may be applied to the inferior oblique in certain cases of overaction.

Myectomy—applied in resection of rectus muscles and in cases of extreme spasms or overaction of the inferior oblique muscle.

Resection or Advancement or Tucking—applicable to any of the recti and to the inferior oblique.

Recession or Retroplacement—applicable to any of the rectus muscles and to the obliques.

PROCEDURES AND TECHNIQUES

TENOTOMY

This consists in free or partial division of a rectus muscle at its tendon insertion. It is applied to the lateral rectus muscle, as, for example, in case of divergence excess. A small incision is made through the conjunctiva overlying the tendon, the latter is isolated and freely divided at or near the insertion. No dissection of Tenon's capsule is made. Simple closure of the conjunctival incision with two plain gut 4-0 sutures is all that is needed. Tenotomy formerly applied in guarded or partial form to the

medial rectus muscle in cases of overaction has been replaced by the operation of recession or retroplacement. Tenotomy of the medial rectus muscle is undesirable because of the usual sequela of divergence and of the appearance of sinking of the caruncle. One can never be sure of the degree of effect of the guarded tenotomy, so for the purpose of the procedure it is better to perform a recession or retroplacement of the muscle.

MYOTOMY

Myotomy, or division of a muscle, is made use of in case of overaction of the inferior oblique. The muscle is severed at its origin at the inferior nasal margin of the orbit. The attachment of the muscle to its investing sheaths prevents its full retraction and permits its action and function to be preserved to a less degree than previously. Myotomy of the inferior oblique at its insertion, however, produces too great an effect, and results in its complete paralysis. Myotomy of a rectus muscle or division of the muscles well behind their tendinous insertions would, if practiced, probably produce a similar undesirable paralytic effect. It is not to be recommended.

Technique of myotomy of the inferior oblique muscle at its origin. An incision may be made through the skin at the inferior nasal margin of the orbit, cutting through the orbicularis and superficial fascia, then through the deep fascia, exposing the orbital contents. A muscle hook is inserted point down back along the floor of the orbit from a point just temporal to the origin of the inferior oblique. The point of the hook is then turned nasalward and placed beneath the insertion of the muscle. The muscle is brought into the section on the inner curve of the hook, is isolated from its investing sheaths, cut across near the

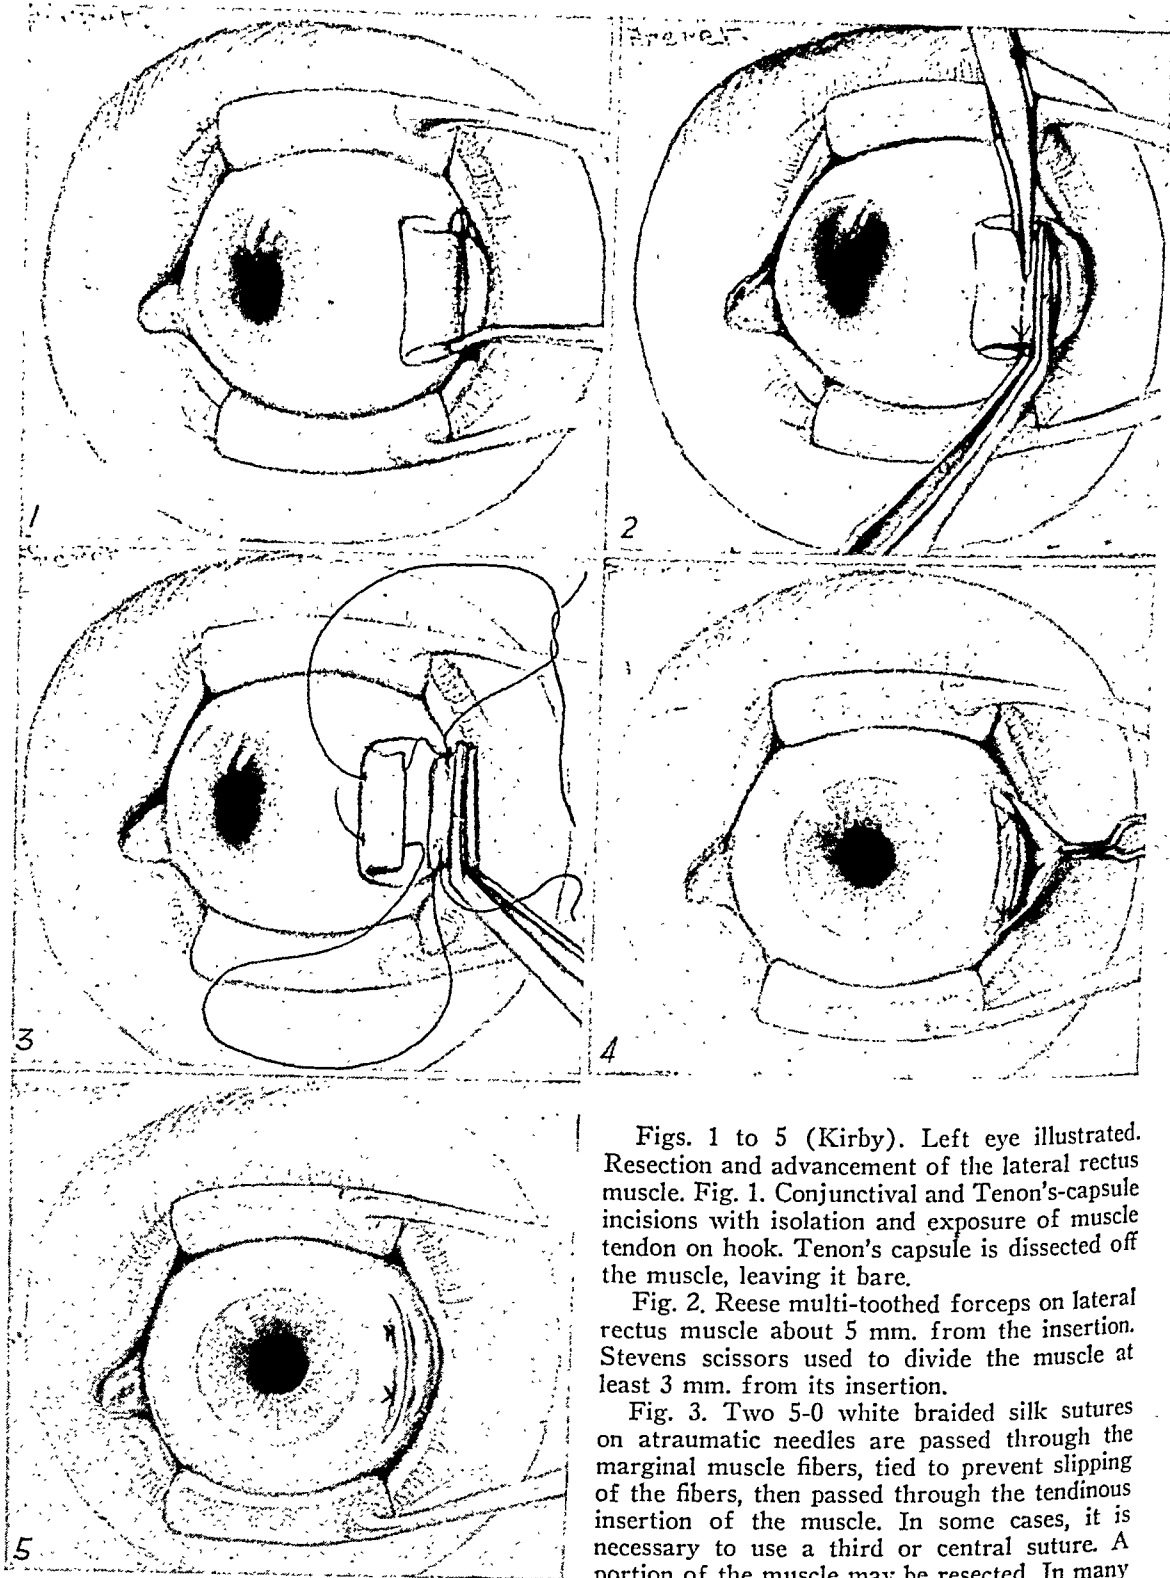

origin, and allowed to retract. The procedure may be varied by making the incision through the lower nasal conjunctival fornix, and exposing the muscle in much the same way as through the skin. For a more accurate or graduated effect in correcting the lesser degrees of overaction of the inferior oblique and for proper balance when both inferior obliques require less action, see the paragraph with the description of the technique of recession of the inferior oblique as developed by White.

MYECTOMY

Myectomy, or removal of a portion of muscle tissue, may be applied in cases of underaction, as, for example, when a portion of the lateral rectus muscle at its tendinous insertion is removed and the remainder is advanced and attached to the previous insertion. Myectomy may also be performed in case of an extremely overacting inferior oblique by removing a portion of the muscle at or near the insertion and allowing the rest of the muscle to retract into its investing fascias.

RESECTION—ADVANCEMENT—TUCKING

The principle of resection, or removal of a portion of a rectus muscle near its tendinous insertion, and advancement of the cut end of the muscle to be attached to the previous tendinous insertion may be applied for the correction of weakness of action of an individual muscle. Shortening the weakened muscle according to various methods of cinching may be used to increase the action and function of the muscle, but I have not often found it necessary to use these procedures. The technique of resection and advancement, which follows in the next paragraph, has well served the purpose. It may be applied to any of the rectus muscles as indicated.

Figs. 1 to 5 (Kirby). Left eye illustrated. Resection and advancement of the lateral rectus muscle. Fig. 1. Conjunctival and Tenon's-capsule incisions with isolation and exposure of muscle tendon on hook. Tenon's capsule is dissected off the muscle, leaving it bare.

Fig. 2. Reese multi-toothed forceps on lateral rectus muscle about 5 mm. from the insertion. Stevens scissors used to divide the muscle at least 3 mm. from its insertion.

Fig. 3. Two 5-0 white braided silk sutures on atraumatic needles are passed through the marginal muscle fibers, tied to prevent slipping of the fibers, then passed through the tendinous insertion of the muscle. In some cases, it is necessary to use a third or central suture. A portion of the muscle may be resected. In many cases, however, this is not necessary. Only the

muscle tissues, not the investing fascias, are included in the sutures.

Fig. 4. The muscle has been advanced and the sutures tied. Further dissection of the conjunctiva is unnecessary.

Fig. 5. The conjunctiva may be closed with interrupted or mattress plain 4- or 5-0 gut sutures.

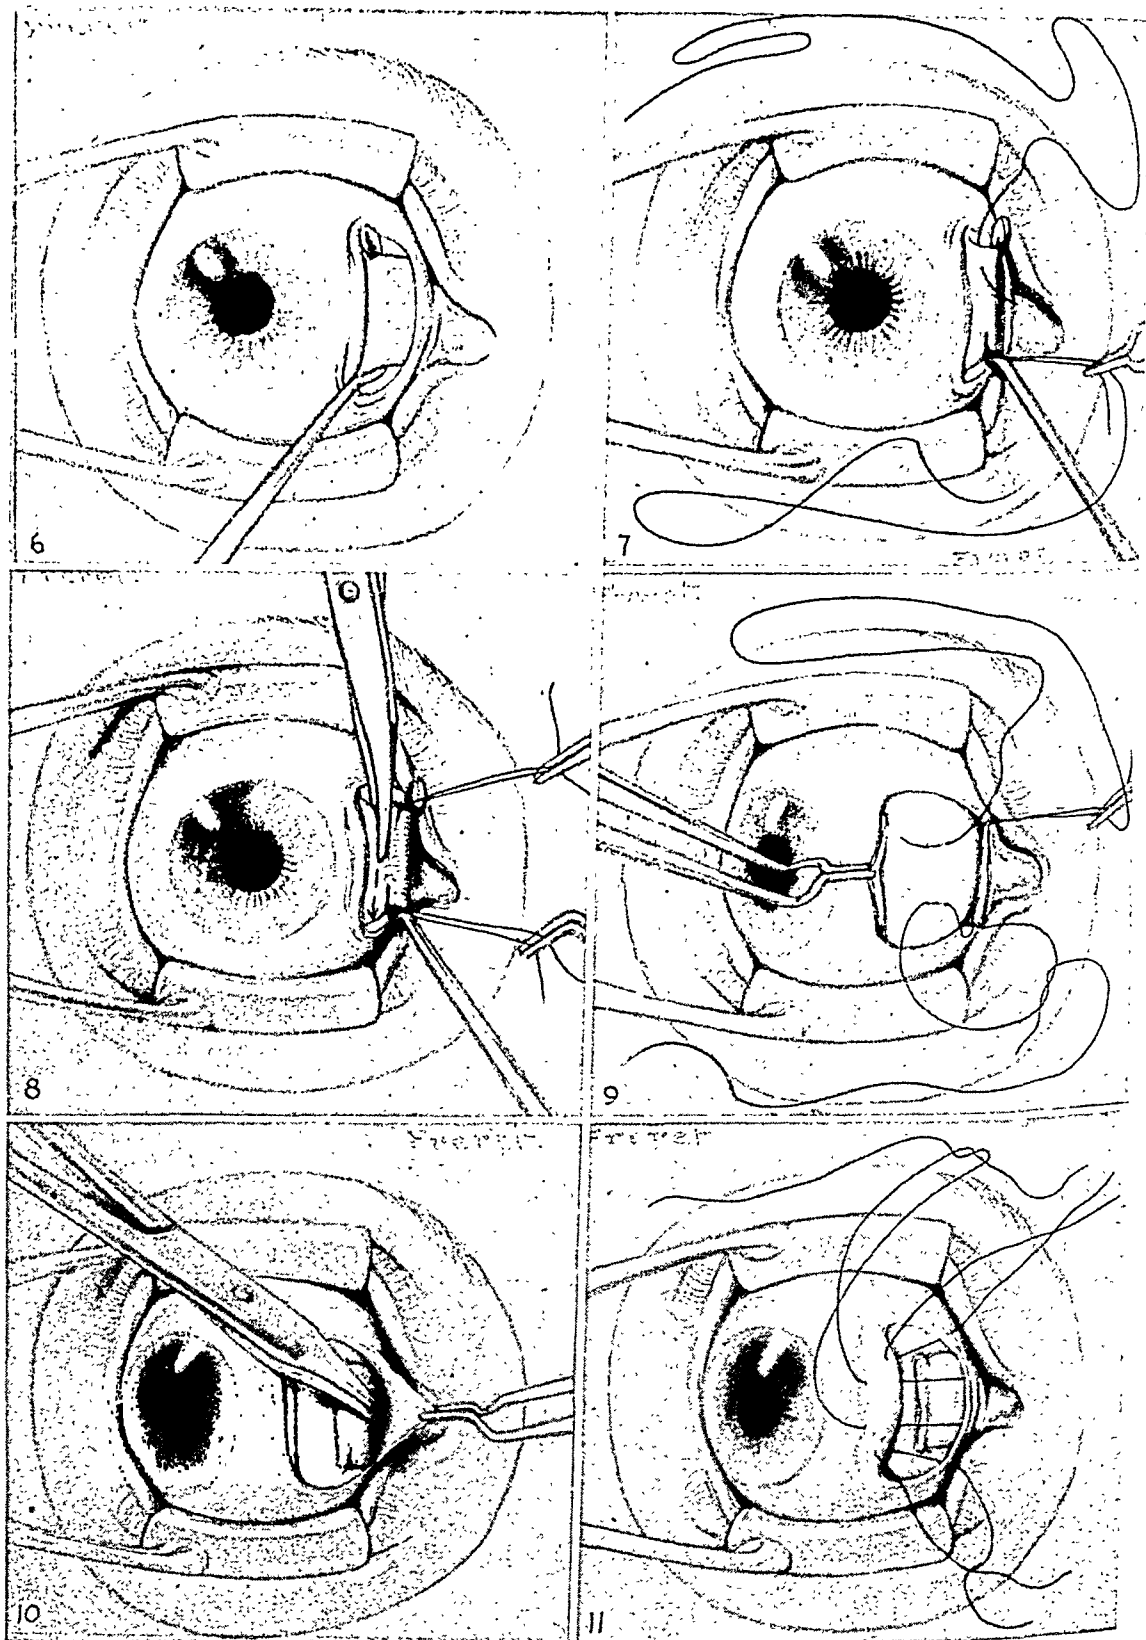

Technique of the operation of resection and advancement of a rectus muscle. The conjunctiva over the tendinous insertion of the rectus muscle is divided, and the Tenon's-capsule sheath of the muscle exposed. The sheath is picked up with forceps at one side of the tendon and buttonholed. Forceps are used to grasp and hold the tendon while a muscle hook is passed accurately and carefully beneath the tendon of the muscle to the opposite side, so that a little tent of Tenon's capsule is raised on the point of the hook (fig. 1). Careful observation is then made to ascertain whether the complete tendon has been included. The close relationship of the inferior oblique insertion to the lateral rectus tendon should be remembered, so that the former will not be included in any procedure. Should this have been done, Tenon's capsule is carefully severed from its attachment to the muscle and stripped back to expose the bare muscle slightly beyond the point at which the resection is to be performed. A muscle clamp with multiple teeth is slipped across the muscle belly at least 4 to 5 mm. from the tendinous insertion and the tendon is severed with scissors so that a 2 to 3-mm. stump is left attached (fig. 2). Then 5-0 white braided silk sutures on atraumatic needles are passed through 2 or 3 mm. of both margins of the muscle belly at the desired opposite points, and a single loop tie is made in each to hold the sutures at these points and prevent their slipping through the muscle fibers (fig. 3). The muscle forceps are then removed and the muscle advanced, the needles being passed from beneath the very insertion of the tendon out through its surface and tied securely, bringing the muscle forward and enhancing its action (fig. 4). A third suture may be used in the center of the muscle and the tendon, if this seems desirable. Very little or no muscle or tendon tissue is removed. There may ap-

pear to be a slight excess of tissue, but when healing has taken place there should be no lump or deformity. The conjunctiva is carefully closed with 4-0 plain gut sutures (fig. 5).

RECESSION—RETROPLACEMENT

The principle of recession or retroplacement may be used to relieve spasm or overaction of a muscle. It is applicable to the rectus muscles and to the inferior oblique at its insertion.

Technique of the operation of recession or retroplacement of a rectus muscle. The operation of recession may be applied to any overacting rectus muscle. The incision is made over the tendinous insertion of the muscle, exposing Tenon's capsule and the muscle. Tenon's capsule at one margin of the tendon is buttonholed, the tendon grasped with forceps, and a muscle hook slipped carefully beneath the tendon to the opposite side where Tenon's capsule is again buttonholed. Then the muscle is denuded of its sheath (fig. 6). Single-armed 5-0 white braided silk sutures on atraumatic needles are passed through the tendon as close to the insertion as possible and a single-loop tie is made to secure the tendon from slipping (fig. 7). The tendon is then carefully severed as close to flush with the sclera as possible, allowing the muscle to retract (fig. 8). Fixation forceps are applied to the exact center of the stump of the tendon, and the point of recession measured from the stump and marked lightly on the sclera with calipers. Then the atraumatic needles and sutures on either side of the muscle are in turn inserted at the marked points, 1 to 1½ mm. of the outer layers of sclera picked up and passed through, and the end of the receded muscle is brought up to the retroplacement point as measured on the sclera. There the sutures are tied carefully in place

Figs. 6 to 11 (Kirby). Right eye illustrated. Recession of the medial rectus muscle. Fig. 6. Isolation of the medial rectus muscle on a hook. Tenon's capsule has been freed from the muscle fibers and dissected back.

(fig. 9). Inspection and observation then confirm whether the exact amount of recession necessary has been accomplished (fig. 10). The subconjunctival tissue is undermined when necessary. This is particularly important if it is the medial rectus muscle that is recessed. The conjunctival incision is closed with interrupted plain 4-0 sutures. In the case of the medial rectus, the central is matted through the conjunctival edge of the semilunar fold, through the stump of the previous tendinous insertion, and through the other edge of the conjunctiva to make sure that the semilunar fold and the caruncle are advanced (fig. 11).

The handling and care of Tenon's capsule and other fascias in ocular-muscle surgery. In all surgery of the ocular muscles, the fascial attachments and the check ligaments must be kept in mind and properly handled to produce the desired results. I have made it a practice to denude the muscles of their Tenon's-capsule sheaths. If Tenon's capsule and particularly the check ligaments are resected, there may result an unwanted limitation of rotation. If the tissues anterior to the medial rectus muscle are receded with the muscle there results a sinking of the caruncle and of the semilunar fold, producing a cosmetic blemish of the appearance of an artificial eye. I repeat that I make

it a practice, after performing recession of the medial rectus muscle, to undercut the semilunar fold and caruncle well back and to bring these tissues forward to be attached to the stump of the previous insertion of the muscle to prevent the sunken appearance. In general, it is well to bear in mind that resection or advancement of a horizontal muscle narrows the palpebral fissure, whereas recession or tenotomy widens it. The superior and inferior recti have important fascial attachments to the upper and lower eyelids, respectively. Resection of the superior rectus muscle with its fascia for correction of hypotropia may narrow the palpebral fissure and produce a partial true blepharoptosis. This may be avoided somewhat if the muscle is dissected clean of its fascia and only muscle tissue resected and advanced. Recession of the inferior rectus muscle may result in lowering the level of the lower eyelid and widening the palpebral fissure, whereas resection of the inferior rectus and its fascia may raise the lower eyelid. The procedure of stripping back the fascia and exposing the muscle tissue itself for the procedures will minify although it will not prevent the undesired changes in the position of the eyelids.

The extent of surgery for strabismus. The degree of resection or recession must

Fig. 7. Two 5-0 white braided silk sutures on atraumatic needles are passed through the margins of the tendon almost directly at the insertion. The sutures are tied to prevent slipping of the fibers.

Fig. 8. While the strands of the suture material are held lightly away, Stevens scissors are used to sever the tendon at its insertion.

Fig. 9. The central portion of the tendon stump is held with forceps. The estimated degree of recession has been accurately marked with calipers. The needles and sutures are passed through the outer layers of the sclera, then the receded muscle is brought to the new attachment to be sutured in place.

Fig. 10. The muscle is shown receded to its new position. To prevent sinking of the caruncle and the semi-lunar fold, these are undermined with Stevens scissors.

Fig. 11. A satisfactory method of closing the conjunctiva. The undermined caruncle and semi-lunar fold are brought forward by a double-armed plain 4- or 5-0 gut suture which is passed through the tendon stump, then through the conjunctiva and tied. Single-armed sutures are used above and below the central mattress suture.

be varied according to the individual case and conditions as demonstrated by pre-operative functional tests as well as by the appearance of the muscles at the time of operation. In general, up to 8 to 10 mm. of a weak muscle may be removed in the procedure of resection and advancement. The recession or retroplacement of a medial rectus muscle should not be over 5 mm., while that of the lateral rectus muscle may be 6 to 7 mm., depending on the size of the eye. Right judgment of the extent of the operation is acquired only through experience in the results obtained, and is affected by the individual surgeon's methods of dissection, the sutures used, the handling of the tissues, and the patient's reaction to surgery.

The sutures used in ocular-muscle surgery. Buried nonabsorbable nonirritating 5-0 braided white silk or 5-0 chromic gut sutures are used in the operation of recession because it has been found by experience that they are superior for the purpose to plain gut, heavier chromic gut, or exposed silk sutures which require removal. The use of plain, absorbable gut sutures for closing the conjunctival incision has proved very satisfactory. They do not require removal. This is a great advantage, particularly in the case of children. The sharp atraumatic needle with the suture welded into its butt end offers great advantages over the older bulkier form of needle that required threading through the eye of the needle.

THE APPLICATION OF SURGERY

Both the usual and unusual types of strabismus will be considered.

SURGERY OF THE USUAL CASES OF STRABISMUS

Recognition and establishment of the correct diagnosis of the various motor anomalies will help greatly and serve as

the proper guide in the application of surgery. Some of the conditions in which surgery may be used advantageously are: (1) Convergence or adduction excess and divergence or abduction insufficiency associated with convergent strabismus. (2) Divergence or abduction excess and convergence or adduction insufficiency associated with divergent strabismus. (3) Vertical deviations existing alone or associated with horizontal deviations and due to weakness or overaction of any one or more of the elevator or depressor muscles.

Cases of esotropia associated with convergence excess. Convergence excess resulting in convergent strabismus may be defined as the condition in which the existing hyperopia of varying degrees induces excess accommodative effort and excessive convergence. For example, if a patient has three diopters of hyperopia, he must exercise three diopters of accommodation for clear vision at infinity, which for practical purposes is at any point beyond 6 meters or 20 feet. This added accommodation and convergence are also exercised at any point of fixation within infinite distance. It is difficult for the patient to maintain fusion under such conditions, and convergent strabismus may result. The inward deviation of the eyes is greater for near than for distance vision. Early correction of the hyperopia in such a case may save the patient from the development of strabismus and loss of binocular single vision. In surgery as applied to cases of esotropia associated with convergence excess there may be indicated recession of one or both medial rectus muscles, although resection or advancement of the lateral rectus is usually necessary in long-standing cases.

Cases of convergent strabismus associated with divergence insufficiency and

unilateral or bilateral abduction paresis.

Divergence insufficiency is a condition in which the function of divergence or returning the eyes to parallelism after any act of accommodation and convergence is less than normal. The deviation is greater for distance than for near vision. The function of divergence may, as an entity, be impaired, or there may be weakness of one or both lateral rectus muscles. In cases of lesser degree, prisms, base out, may give relief; however, if of greater degree than can be dealt with by prisms and fusional reserve, or if convergent strabismus with weakness of abduction is present, surgery is indicated. Resection of the lateral rectus in one or both eyes may be necessary. A secondary overaction of one or both medial rectus muscles may also indicate the necessity of recession or retroplacement of one or both of the medial recti. Fibrosis of the medial rectus may produce convergent strabismus and stimulate paralysis of the lateral rectus muscle. Recession of the fibrosed muscle may help much in producing cosmetic and functional improvement.

Cases of divergent strabismus associated with divergence excess.

Divergence excess is a condition in which the eyes instead of returning from convergence to parallelism on relaxation from near to distance fixation may actually deviate outward. The deviation is greater for distance than for near. Normal power of convergence may be present. Usually fusion is maintained, and the strabismus, if present, is intermittent indefinitely or for a long while before it becomes constant. The prognosis with surgery is good. Recession or tenotomy of one or both lateral rectus muscles may be indicated. It is usually unnecessary to touch the medial rectus muscles.

Cases of divergent strabismus associated with convergence insufficiency and adduction insufficiency. Convergence insufficiency is a condition in which the stimulus from the convergence center may be weak, although the medial rectus muscles themselves, individually, also may be paretic. The divergent strabismus that results is greater for near than for distance vision. It may be improved by convergence exercises and by appropriate lenses. The condition is difficult to correct by means of surgery, even when the principle of advancement or resection of the medial rectus muscle, one or both, is applied. It is usually necessary in marked cases of divergent strabismus due to convergence insufficiency to perform also a tenotomy or recession of one or both of the lateral rectus muscles.

Vertical deviations of the eyes. Hyper tropia and Hypotropia.

Vertical deviations are those in which hypertropia or hypotropia exists because of weakness or overaction of one or more of the elevator or depressor muscles. A common example is that of hypotropia due to weakness of a superior rectus muscle. If the patient elects to fixate with the paretic eye, however, overaction or spasm of the inferior oblique of the fellow eye usually results. This condition may be bilateral and alternating. If both elevators of one eye are paretic, the sound eye usually fixates and the paretic eye is found in a position of hypotropia. Vertical deviations may develop as a defense mechanism, the patient involuntarily moving one of his eyes to a position where its image will least interfere with that of the fixating eye. Vertical deviations may be associated with horizontal deviations. Surgery may be applied for the correction of vertical deviations in the form of tenotomy, recession, resection, or advancement of the overactive vertical muscles, as indicated. Resection

or advancement of the paretic muscle or muscles will probably not alter the fixation with the paretic eye, and the phenomenon of overaction of the muscles of the sound or fellow eye will remain.

Spasm of the inferior oblique muscle. Ocular torticollis. Spasm or overaction of the superior rectus or of the inferior oblique muscle with variable hypertropia may develop in cases of paresis of one or more elevator or depressor muscles. It is commonly seen with paresis of the superior rectus, and may be unilateral or bilateral. It is probably an expression of the patient's effort to avoid diplopia. The phenomenon of ocular torticollis with head tilting and rotation is often associated with inferior oblique and superior oblique muscle anomalies. In such cases the orthopedist will do well to have the ocular condition examined and corrected first before the sterno-cleido-mastoid muscle is touched. The spasm or overaction of the inferior oblique muscle may be corrected by free myotomy or myectomy at the origin of the muscle as indicated by the degree of overaction of the muscle, or the approach may be made at the insertion, the muscle being recessed according to the technique of White.¹ In case of inferior oblique paralysis with overaction of the superior rectus of the fellow eye, recession of the overactive superior rectus muscle is in order.

SURGERY OF UNUSUAL CASES OF STRABISMUS

Transplantation of superior and inferior rectus muscles in case of paralysis of the lateral rectus muscle. If there is congenital paralysis of the lateral rectus muscle in which convergent strabismus exists with flaccid, atrophic lateral rectus muscle, or if the muscle tissue has been replaced by fibrous tissue, resort may be had to transplanting the lateral half

of the superior and inferior rectus muscles by means of a simple technique. After a conjunctival incision has been made over the lateral rectus, the condition of the muscle is evaluated. If any well-functioning lateral rectus muscle tissue is present it may be resected and advanced. If the tissue is flaccid and atrophic it is not disturbed, but if it is replaced by fibrous tissue, the latter is removed. Through the lateral conjunctival incision, which need not be enlarged for the transplantation of the superior and inferior rectus muscles, a hook is passed to engage the superior rectus and to bring it into the field of operation. A white 5-0 silk suture is passed through, looped around the outer half of the superior rectus tendon, and tied once to secure the fibers from slipping. Then with de Wecker scissors the outer half of the tendon is severed and the muscle split about 10 mm. backward. The same procedure is applied to the inferior rectus; and two transplanted half muscles are sutured to the lateral rectus stump. It is usually also necessary to perform a recession of the medial rectus muscle.

Reconstruction in cases wherein an overcorrection has followed surgery for the correction of strabismus. Although temporary overcorrection may be necessary to achieve results in some cases of divergence excess, it is wise to use every precaution to avoid overcorrection in cases of convergent strabismus. Eyes in the former case adapt themselves readily, usually regaining fusion with sufficient amplitude; if reattachment of the recessed lateral rectus does not occur, the overcorrection may right itself and the final result vary from orthophoria to a moderate degree of exophoria. Overcorrection may develop in cases of divergence excess with good power of convergence if the medial rectus is advanced

or if exsection of lateral-rectus tissue is performed. Cases of divergent strabismus due to convergence insufficiency are difficult to overcorrect although it is possible. Cases of convergent strabismus due to divergence insufficiency with paresis of divergence or with paresis of one or both lateral rectus muscles and those due to convergence excess may be overcorrected (1) if too much lateral rectus muscle tissue is resected, (2) if Tenon's capsule or the check ligament of the lateral recti are included in the resection or advancement, (3) if a complete tenotomy of the medial rectus is made at its insertion, or (4) if it is recessed too far back from its insertion so that it cannot exert its proper action. The cosmetic blemish and the functional disturbances from overcorrection are very disturbing to the patient and to his relatives.

The use of Tenon's capsule transplants in cases of overcorrection and abnormal muscle adhesions. The measures undertaken for repair of overcorrection were in general unsuccessful until the principle of Tenon's-capsule transplant for the relief of muscular adhesions hindering muscular action was employed. The ability to bring a muscle anterior to a previously placed normal or abnormal or adventitious insertion in the sclera was exemplified by Berens.² If the denuded area on the sclera from which is removed the abnormally retroplaced or adherent muscle is not covered by Tenon's capsule, the attempt to move the muscle forward to a new or more anterior insertion will fail, for an adhesion will form between the belly of the muscle and the denuded area where they come in contact. The insertion will remain where it was and the muscular action and function or effect will not be improved or not sufficiently improved to be satisfactory. The technique of covering the denuded area of

sclera with a free or pedunculated or sliding graft of Tenon's capsule, utilizing tissue to which the muscle is normally accustomed as a sheath and to which it will not adhere is well described by Berens. Its employment can be definitely recommended from my personal experiences.

The surgical correction of strabismus fixus. As a result of congenital anomaly, or prenatal or postnatal inflammation or trauma, there may develop strabismus fixus with adhesions of varying degree and extent between the globe and the walls of the orbit. Such conditions are necessarily difficult to correct; they require severance of the adhesions and sliding grafts of Tenon's capsule to cover the denuded areas in order to prevent their re-formation.

Surgical reconstruction necessary in cases of replacement of muscle tissue by fibrous tissue. As a congenital developmental anomaly or because of inflammation or trauma, normal muscle tissue may be replaced by fibrous tissue in whole or in part. This condition causes limitation of rotation in the field of action of the involved muscle and retraction when the antagonist muscle, if normal, is activated. The most familiar retraction syndrome is that of the enophthalmos produced on adduction of the affected eye by the medial rectus muscle when the lateral rectus muscle has been replaced by fibrous tissue. I have in such cases performed either a recession of the medial rectus for partial correction of a manifest convergent strabismus or have removed the fibrous tissue and transplanted the lateral halves of the superior and inferior rectus muscles and combined this procedure with a recession of the medial rectus muscle. I have seen replacement of the superior rectus muscle as the cause of paralysis of elevation with

ptosis. There was retraction of the globe on downward gaze. If there is definite hypotropia, recession of the inferior rectus may be done. Fibrosis of the medial rectus may cause convergent strabismus and simulate paralysis of the lateral rectus. Exposure of the muscles at the time of the operation may reveal good muscle tissue in the lateral rectus muscle. In such a case, recession of the fibrosed medial rectus and resection of the lateral rectus are in order.

Surgical reconstruction of cases of paralysis of elevation with real or pseudoblepharoptosis. Certain cases may, as a congenital anomaly, or due to hemorrhage or trauma, exhibit a condition of unilateral or bilateral hypotropia with real or pseudoblepharoptosis. There is a paresis or paralysis of the superior rectus and of the inferior oblique muscles. Subjective and objective tests will disclose whether the blepharoptosis is real or pseudo. The decision may be made whether the lid is down because the eye is down and that it will lift when the eye is elevated by the surgical procedure of shortening the paretic or paralyzed superior rectus and inferior oblique muscle tissues. In the latter case, no further operation may be necessary for the correction of the blepharoptosis. The superior rectus may be resected and advanced according to the technique given under the foregoing heading, "*The technique of the operation of resection and advancement of a rectus muscle.*" The resection and advancement of the inferior oblique is best performed through a curvilinear skin and fascial incision at the inferior margin of the orbit. The muscle is exposed and, after being secured with two 5-0 white braided silk sutures or 4-0 10-day chromic gut sutures, is severed from its insertion and advanced over the orbital bone and secured to the periosteum

of the nasal bone in a bed which has been dissected for the purpose. The orbital fascia is closed by a third white silk suture and the skin by a subcuticular, sliding 5-0 black suture. This technique except for the suture material was developed and used by Wheeler.³ These procedures have been satisfactory for the correction of a bilateral case of this condition with pseudoptosis.⁴ A variation of the approach to the inferior oblique might be made by resecting and advancing the inferior oblique at its insertion.

SUMMARY AND CONCLUSIONS

The personal training and experiences of the author in handling cases of strabismus have been given in detail. Careful preoperative study of the patient's monocular vision, refraction, accommodation, convergence, divergence, monocular and binocular uncover tests both in primary as well as in the six cardinal positions of gaze, degree of fusion if present, proper diagnosis, and the use of orthoptic exercises with corrective lenses, when indicated, are necessary before surgery.

This may well be performed at an early age if correction of the strabismus is not obtained by orthoptic measures. The plan of operation may be made before the incisions are begun, but the actual details of the procedure and the extent of the surgery may not be evident before exposure and examination of the muscles. It is well not to have any routine technique in mind, but to vary the procedures individually according to the case under observation. It is best not to operate on too many muscles at one time and particularly not to do too much. It is better to have an undercorrection that is amenable to further correction than to be confronted with an overcorrection that is difficult to reconstruct. A conservative approach is best. If a secondary operation

seems necessary, it is best to allow sufficient time to elapse so that the tissues may heal and resolve before the next procedure is attempted.

The techniques which have been satisfactory in diminishing the function of an overactive muscle by tenotomy, myotomy, myectomy, and by recession or retroplacement and those which have been found good in enhancing the action of weak muscles by advancement or resection, have been described in detail and original illustrations have been used to clarify further the methods. Particular stress is given to the proper handling of the conjunctiva, of the muscles of Tenon's capsule and the other fascias and to the methods of suturing.

The usual cases of convergent strabismus arising from convergence excess or divergence insufficiency, or divergent strabismus arising from divergence ex-

cess or convergence insufficiency, of vertical deviations of the eyes due to paresis of the superior rectus and associated overaction of the inferior oblique of the fellow eye as well as the unusual cases of paralysis of extrinsic ocular muscles, of different cases of overcorrected strabismus, strabismus fixus, replacement of muscle by fibrous tissue, and finally the condition of paralysis of elevation, have all been discussed and the indications for surgery outlined.

The problems of diagnosis are stressed to avoid the pitfalls of application of unsuitable procedures. Proper care and orthoptic training after surgery are urged to achieve satisfaction and to accomplish the greatest goal, binocular single vision with depth perception whenever this is possible.

A CENTER FOR OCULAR DIVERGENCE: DOES IT EXIST?*

RICHARD G. SCOBEE, CAPT. (MC), A.U.S., AND EARL L. GREEN, CAPT. (AC), A.U.S.

Randolph Field, Texas

The existence of a center for ocular convergence in the brain is well established.¹ Evidence for the existence of a separate center for ocular divergence, presented by Bruce,² is much less convincing. The convergence center has been located anatomically by Bender and Weinstein,³ but no anatomic location has been demonstrated for a divergence center.

Arguments for the existence of a divergence center, short of its anatomic localization, come from many sources. Our purpose is threefold. First, we shall review these arguments and demonstrate that they do not necessarily require the existence of a divergence center. Second, we shall present an argument that the results of the disruption of fusion in the tests for heterophoria may be interpreted in terms of a single convergence center rather than in terms of two separate centers, one for convergence and the other for divergence. Third, we shall present the elasticity theory of divergence and arguments in its favor.

ARGUMENTS FOR A DIVERGENCE CENTER

One interpretation of divergence has been expressed by Duane⁴ when he defined it as that function by virtue of which the visual lines, when converged on a near object, are made to separate in order to sight a more remote object. According to this interpretation, divergence is merely a change from a state of greater convergence of the visual lines to one of lesser convergence and, for this reason, is often referred to as a relaxation

of convergence or negative convergence⁵ instead of divergence.

A more literal interpretation of divergence would be that function by virtue of which the visual lines are actually made to diverge one from the other, with divergence beginning where negative convergence ceased; that is, the visual lines are parallel. The existence of such true divergence is not too much to expect if there actually is a separate center in the brain for divergence, functioning as an antagonist to the convergence center.

The arguments for the existence of a separate center in the brain controlling the divergence function have been summarized.² The evidence is derived from three sources: (1) phylogenetic, (2) physiologic, and (3) pathologic.

Phylogenetic evidence. Bruce² first asks the question, whether there is a function the existence of which predicates the existence of divergence and to the working of which divergence is indispensable. He answers that the function of convergence seems to fulfill this requirement. He points out that convergence without divergence would be a crippling liability as well as a biologic weakness and, further, that nature tends to suppress biologic weaknesses. The presumption is, therefore, that convergence and divergence appeared simultaneously on the phyletic scale. Since the nucleus of Perlia, the accepted center for convergence, is the last-known nucleus to become differentiated,⁶ its appearance must coincide with the appearance of divergence, according to Bruce.

In phylogeny, any function furthering fusion has been accentuated and all others have been suppressed. Hence, says

*From the Departments of Ophthalmology and Statistics of the Army Air Forces School of Aviation Medicine.

Bruce, divergence is an essential link in the fusion chain and has been maintained. As a further proof of the essentiality of divergence in fusion, he says that "... in carrying out divergence the healthy eyes will, with unerring precision, fix the object sought. Diplopia must be accepted as the sine qua non of ocular paralysis in a previously binocularly sighted person. . . . In paralysis of divergence, diplopia supervenes, and it is therefore necessary to look on the function of divergence as an essential agency in maintaining fusion." The justification for bringing in divergence paralysis under phylogenetic arguments is not quite evident. He mentions divergence paralysis later, however, under pathologic arguments where one would more logically expect to find it.

Physiologic evidence. Bruce says "... True fusion connotes the ability to focus the visual axes on points at varying distances, and the function of divergence is the sine qua non of this ability." He thus seems to accept Duane's interpretation of divergence, and then reaches the crux of the matter by posing the question: Is divergence active or passive? His answer is that if it is entirely passive, the position of rest should invariably be divergent. Maddox⁷ who believed that divergence was active, nevertheless says of the divergence reflex "... the only one I have not been able to prove positively." It has been pointed out that the eyes *are* divergent in deep sleep⁸⁻¹² or narcosis,^{8, 10, 11} in death before rigor sets in, and in cases of blindness,⁸ and even in cases of innervational esotropia under anesthesia.¹²

If, on the other hand, divergence is active, Bruce reasons that testing divergence with prisms should, and does, lead to "... the same sense of strain" as when convergence is tested with prisms.

Perhaps the "sense of strain" in any prism vergence test comes from the individual's unusual experience in attempting to overcome a threatening diplopia by the use of the fusion process rather than from the strain on any one particular set of extraocular muscles. Bruce admits that Landolt¹³ was right in stating that divergence cannot be increased by exercise. If divergence is active rather than passive, it seems strange that it cannot be increased by exercising with prisms of gradually increasing strength placed base in. Bruce's opinion, however, is that divergence is active rather than passive.

Finally, he remarks that if divergence is entirely passive, it should begin rapidly and then progress more slowly. Since divergence (as defined by Duane and interpreted by Bruce) occurs at a uniform speed, it must be active. He then brings forth a mild contradiction by postulating that when divergence is first initiated, the external rectus muscle is stretched and *does not contract actively* (italics our own); the initial passive abduction is checked, he says, by finely graded tonic movements of the medial rectus. As divergence proceeds, the external rectus begins to contract to an increasing degree. This would seem to be an admission that divergence is at least passive at the outset of movement—in spite of his former statement that divergence is active, not passive. Duane⁴ believed that divergence had both active and passive components.

According to Cridland,¹⁴ there are three records in the literature of potential voluntary divergence.^{15, 16, 17} Of these, Cridland says that the first two suggest an extreme degree of voluntary inhibition comparable to the fakir's control of pain or the same phenomenon in firewalkers. How is it possible, he asks, to differentiate between voluntary excitation of one

set of muscles and voluntary inhibition of another set by introspection alone? Hansen Grut⁸ said "... no one is able to bring about a divergence of the two eyes ... because the habit and practice of such a movement is altogether absent."

On the other hand, the abduction of one eye while the other fixates is frequent, according to Bruce, who, in turn, cites Willbrand and Saenger,¹⁸ Spiller,¹⁹ and Reese.²⁰ Bruce himself has seen two such cases in patients of whom he says "... they were obviously relaxing their accommodation and convergence and thus allowing their eyes to return to what was for them the position of rest." In the same connection, Livingston²¹ refers to "... an ocular fatigue of sufficient amount to produce a palpable exophoria." Yet Bruce has said previously that the position of rest would be one of divergence *provided* divergence were passive, but that divergence is not passive but active! To quote Bruce further, "Divergence then, while partially an active process, is not a volitional function. It is obvious, however, that it is dependent on volitional impulses for its initiation." This is somewhat confusing, to say the least. Finally, if divergence is dependent on volitional impulses for its initiation, he finds an explanation by citing Hering, who stated that the motivation of divergence lay in attention!

Pathologic evidence. The only factual argument put forth by proponents of the existence of a divergence center is the clinical entity known as "divergence paralysis." Von Graefe²² reported the first case, and Smith²³ the second. It was Parinaud²⁴ who first put the entity on a logical basis, and finally Duane²⁵ described it in classic fashion. The etiology of divergence paralysis varies but is usually a disease of the brain such as encephalitis, syphilis, tabes, multiple sclerosis, lead poisoning, hemorrhage,

hysteria, diphtheria, poliomyelitis, chorea, or metastatic carcinoma.

Bielschowsky¹¹ listed seven characteristic findings in divergence paralysis: (1) homonymous diplopia for all objects beyond a certain distance, usually 10 to 20 inches; (2) the angle of squint remains unchanged or decreases slightly in secondary positions of gaze; (3) if an object is brought near to the patient, the two images approach each other and finally fuse when the object is 10 to 15 inches away; (4) when the object is brought still nearer, insufficient convergence causes crossed diplopia; (5) prisms base out give binocular single vision throughout the entire field of fixation and at any distance; (6) there is no restriction of the field of fixation of either eye; and (7) the angle of squint is relatively constant on repeated examinations. Bielschowsky, however, admits that he is forced to agree with Alfred Graefe²⁶ and Berry²⁷ that "divergence paralysis" might well be convergence spasm instead, although he is sure that a divergence innervation exists. He further says that his most characteristic cases of "divergence paralysis" developed quite suddenly into frank, bilateral sixth-cranial-nerve paralyses!

Bruce lists two other anomalies of divergence in addition to "divergence paralysis." One of them, divergence insufficiency, he says is due to a progressive convergence excess, in most cases. The other, divergence excess, he says is a true innervational anomaly and gives Bielschowsky²⁸ as a reference; in the next sentence, Bruce says that "... the etiology is obscure," and admits that "... one type of divergence excess is a sequela of convergence weakness." How any of these anomalies of divergence are conclusive arguments for the existence of a divergence center is difficult to see, since all three of them could well be con-

vergence anomalies instead.

In summation, Bruce quotes Gould²⁹ who defines a center as "... the ganglion or plexus whence issue the nerves controlling a function." He then reasons that a divergence center must exist, having arrived at this conclusion by a process of deduction. It is axiomatic, he says, that no function of importance is without its center. As a point in passing, one wonders about the function of accommodation; a center for positive accommodation has been demonstrated anatomically³ but as yet there has been demonstrated no center antagonistic to positive accommodation. "Given a state of convergence, lateral divergence must obviously be carried out by (1) elasticity, and/or (2) actual contraction of the external rectus. The roles played by these processes have already been discussed and it has been found that the major part is played by the latter of these two possibilities," says Bruce. His statement "... it has been found" is based purely on deductive reasoning. He concedes that actual contraction of the external rectus occurs only as a result of innervation which can come from (1) the sixth-cranial-nerve nucleus, or (2) other sources. Since, in divergence paralysis, the sixth nerves are intact (at least for a time), the source of the innervation must be "other." The "other" is a divergence center which is probably in the midline, concludes Bruce.

The arguments presented for a divergence center can be briefly summarized: (1) phylogenetic—divergence must have developed as a necessary antagonist of convergence and both have been maintained in the interests of fusion; (2) physiologic—divergence is active and hence must have its own innervational center; and (3) pathologic—since "divergence paralysis" is known, it must be produced by a lesion in the divergence center.

EVIDENCE FOR ONE CENTER ONLY

If two separate centers actually exist in the brain for the control of ocular convergence and ocular divergence, this fact should be demonstrable by experimental techniques. Localization experiments similar to those performed by Bender and Weinstein³ may establish the presence of a center for convergence, but failure to locate a center for divergence by such a technique is not evidence that such a center does not in fact exist. Evidence that one center alone is sufficient to account for the functions of both divergence and convergence must come from other types of experiments. The experimental disruption of fusion, such as is produced in heterophoria testing, provides evidence that only one center exists.

The mere fact that numerous tests for heterophoria exist, each with its ardent advocates, is proof that no one test is completely satisfactory. The works and ideas of all those who have written on heterophoria show marked differences in concept and opinion. Dobson³⁰ believes that all lateral-muscle imbalances are errors of convergence and all tests for heterophoria are convergence tests. Prangen,³¹ in contrast to Dobson, believes in a divergence and a convergence mechanism; he thinks that when exophoria is present it is because the divergence mechanism is dominant. Conversely, when esophoria is found, the convergence mechanism holds sway.

Tests for heterophoria. Because of the multiplicity of tests for heterophoria, it is necessary to digress at this point to describe the tests used for the present study. These were (1) the Maddox-rod test, and (2) the screen-Maddox-rod test.³²

The Maddox-rod test is so widely known that it needs little description. While the examinee looks at a spot of

light (a muscle light), the Maddox rod is placed before one eye and the subject asked to adjust, by means of a Risley rotary prism, the position of the line of light to a point where the line bisects the light. Several moments of waiting are often necessary until all movement of the line has ceased. A reading is then taken in prism diopters directly from the calibrated rotary prism frame.

For determining heterophoria with the screen-Maddox-rod test, the Maddox rod is placed before one eye. The examinee is then directed to fixate the muscle light, and a cover is placed before the eye behind the Maddox rod. The cover is removed regularly for a period of one second at about three-second intervals, the other eye, meanwhile, being allowed to maintain fixation constantly. The purpose of this very brief uncovering or "flashing" of the eye behind the Maddox rod is to weaken further the fusion control. If the eye is left uncovered for any but the briefest of periods, various innervations begin to appear which produce a fluctuation of the deviation with a consequent shifting or jumping about of the image of the line. The examinee adjusts the flashing line to a position where it bisects the light, again with the use of a Risley prism, and the deviation is then recorded in prism diopters.

Each of these tests is highly reproducible, provided an identical testing technique is used under identical testing conditions.^{14, 33}

Esophoria and Exophoria. If esophoria and exophoria are separate entities, the independent existence of each could easily be construed as an argument for the existence of separate centers for convergence and divergence, respectively. If, on the other hand, they are interdependent and have no separate existence—that is, esophoria being the result of an in-

creased convergence innervation and exophoria a result of a decreased amount of this same convergence innervation—the evidence for a single convergence center is considerably strengthened.

These two types of heterophoria tests, as Adler¹² has pointed out, will give different measurements, depending on the extent to which they eliminate the visual fusional stimuli. The Maddox-rod test measures the effectiveness of dissimilar retinal images for holding the eyes straight relative to the effectiveness of similar images. The screen-Maddox-rod test measures the effectiveness of monocular retinal stimulation relative to the effectiveness of stimulating the two retinas simultaneously. With the screen-Maddox-rod test, if esophoria and exophoria are separate entities, the added dissociation produced between the two eyes by the addition of screening to the test should uncover more esophoria and more exophoria than when screening is not used. If, on the other hand, esophoria and exophoria are simply different degrees of a single property, then screening may reveal more of one but less of the other.

This is a question which may be answered by testing a group of subjects with and without screening during the Maddox-rod test.

Effect of screening and not screening. An experiment was designed so that the difference between screening and not screening could be observed in eight different testing conditions. One of these testing conditions, for example, called for a testing distance of 20 feet with a red Maddox rod before the dominant eye (20-D-R). Another condition called for the same testing distance but with a white Maddox rod over the dominant eye (20-D-W). All eight of the testing conditions are listed in detail in table 1.

Fig. 1 (Scobee and Green). Distribution of heterophorias (scale in prism diopters) of 100 subjects tested: A, with screening, at 20 feet; B, without screening, at 20 feet; C, with screening at 13 inches; D, without screening, at 13 inches.

For each condition, the results of testing 100 healthy young male subjects, both with and without screening, are described by averages and standard deviations. The standard deviation has been chosen as a

measure of variability even though the distributions of heterophoria on a scale of diopters are slightly asymmetrical.

For the test 20-D-W performed without screening, the amounts of hetero-

phoria uncovered averaged 1.11 prism diopters of esophoria. The standard deviation was 2.40 prism diopters. The frequency distribution of the 100 heterophoria readings is shown in figure 1B, where it may be seen that the readings vary from 3 prism diopters of exophoria to 11 prism diopters of esophoria. For the same test, 20-D-W, performed with screening, the average was 1.58 prism diopters of esophoria and the standard deviation was 2.67 prism diopters (fig. 1A). The effect of screening was to pro-

the dispersion is greater with screening than without screening, this is evidence that screening uncovers more esophoria and more exophoria. If, on the contrary, the dispersion remains essentially the same with screening as without screening, this is evidence that screening merely causes a shift in the total distribution toward *more* esophoria, but *less* exophoria. An analysis of the heterophoria records for increases in dispersion accompanying the use of screening shows that there are no consistent increases or,

TABLE 1

AVERAGE HETEROPHORIAS AND STANDARD DEVIATIONS IN PRISM DIOPTERS OF EIGHT VARIATIONS OF THE MADDOX ROD TEST, WITH AND WITHOUT SCREENING. NUMBER OF CASES, $n=100$

Test	Averages			Standard Deviations			Correlation Coefficient
	Without Screening	With Screening	Difference (with—without)	Without Screening	With Screening	Difference (with—without)	
20-D-R	+1.49	+1.80	0.31	2.67	2.65	-0.02	+0.88
20-D-W	+1.11	+1.58	0.47	2.40	2.67	+0.27	+0.90
20-N-R	+1.55	+1.89	0.34	3.07	2.98	-0.09	+0.96
20-N-W	+1.33	+1.70	0.37	2.38	2.90	+0.52	+0.88
13-D-R	-5.33	-4.97	0.36	5.52	5.29	-0.23	+0.87
13-D-W	-5.33	-4.44	0.89	5.53	5.24	-0.29	+0.89
13-N-R	-5.04	-4.99	0.05	6.07	5.66	-0.41	+0.84
13-N-W	-4.99	-4.70	0.29	5.78	5.75	-0.03	+0.83

+means esophoria (for averages only).

-means exophoria (for averages only).

20=testing distance of 20 feet.

13=testing distance of 13 inches.

D=Maddox rod over dominant eye.

N=Maddox rod over nondominant eye.

R=Red Maddox rod.

W=White Maddox rod.

duce, on the average, 0.47 prism diopters' increase of esophoria in this test.

Using the other seven testing conditions, listed in table 1, comparable differences between screening and not screening in the Maddox-rod test were found. In general, the use of screening in heterophoria testing will uncover about 0.37 prism diopters more of esophoria when the Maddox rod is used (0.37 is the average difference for all eight testing conditions).

A change in the average heterophoria reading may be accompanied by a change in the dispersion about the average. If

for that matter, no general change of any sort in dispersion associated with the use of screening (table 1). The difference between screening and not screening is, therefore, regarded as a difference in the average amount of heterophoria that may be uncovered, and the average change is such that more esophoria and less exophoria are uncovered when screening is used.

A more complete statistical analysis of the data of this study has been reported previously.³⁴

Considering anatomic factors alone, the two eyes should be divergent, but in the

absence of pathologic change, except in deep sleep or narcosis, the eyes never diverge but always converge in varying degrees. This convergence is the result of a constant convergence innervation arising from the convergence center (nucleus of Perlia). The presentation of dissimilar images of the same object to the two eyes by using a Maddox rod dissociates the eyes only partially, and the convergence center is thrown out of balance by a comparable amount. The addition of screening to the Maddox-rod test produces further and greater upset of the convergence innervation arising from the convergence center. The monocular-fixation reflex is still acting powerfully, since only one eye is being screened, and the convergence center in an attempt to correct for this added imbalance responds with even more convergence innervation. The result should be—and is—increased esophoria or decreased exophoria, depending upon which of the two was present from the beginning.

THE ELASTICITY THEORY

The results of the experiment on measuring heterophoria, using a Maddox rod with and without screening, require a re-examination of the vergence mechanism. The results cannot easily be explained by the concept of two vergence centers. Another concept, requiring only one vergence center and compatible with other facts of ocular function, is needed. The elasticity theory of ocular divergence is such a concept.

The fact that pure convergence needs an antagonist in the sense of a movement in the opposite direction is obvious. This antagonistic force may be called "divergence," since the term is a familiar one. Duane's⁴ definition of divergence as that function by virtue of which the visual lines, when converged on a near object, are made to separate in order to sight a

more remote object, is acceptable. This definition may be accepted and yet imply nothing about the origin of the divergence function.

Haessler³⁵ states that one must distinguish the action of diverging from divergence conceived of as a well-established functional unit of the binocular neuromuscular system for whose performance an anatomic structure exists in the brain. In other words, recognize divergence as a movement but be careful to what source you attribute its production. He states that it is not at all necessary to assume that such a functional unit for divergence exists. Faith in the existence of divergence as an independent function, says Haessler, is increased by habitually thinking of convergence and divergence in terms of an oversimplified scheme of opposing forces acting only in a horizontal plane. When a more complex movement is considered, such as carrying the eyes up and out, the accomplishment of a final precise adjustment by means of the same simple stimulus to divergence as is active in a horizontal plane is hardly imaginable because the 12 extraocular muscles would have to be stimulated and inhibited in entirely different proportions.

Any factor short of an actual center for divergence which would logically explain all of the observed phenomena of divergence should be acceptable, particularly since no divergence center has ever been demonstrated. If divergence is innervational in origin and hence active, then a center for divergence is most certainly indicated. If, on the other hand, divergence is passive, one must offer an explanation of how this could possibly be. Let us, therefore, assume that divergence is entirely passive in the sense of there being no divergence innervation, and that it occurs only passively in the sense that it is solely a result of elasticity of the

orbital structure, and then consider the available facts to see whether such an assumption is warranted from the standpoint of anatomy and physiology.

Anatomic. A consideration of the position of the eyes relative to each other, taking into account only the structure of the orbits and their contents, points to a state of divergence of the visual lines. The medial orbital walls are roughly parallel and both parallel the sagittal plane of the head.³⁶ The lateral orbital walls, on the other hand, make an angle of almost 90 degrees with each other or one of 45 degrees with their respective medial walls. Thus each orbital axis makes an angle of roughly 23 to 25 degrees with the sagittal plane of the head. The axis of the muscle cone within the orbit just about coincides with the orbital axis and hence it also makes approximately a 25-degree angle with the sagittal plane of the head. The four recti muscles are all about 40 mm. in length and all take origin from the annulus of Zinn about the optic foramen at the orbital apex.

Thomson³⁷ said "... the eyes lie in an anatomically divergent position—the cadaveric position." Similarly, Chavasse³⁸ "... the anatomical position of the eyes—the position of absolute or dead rest—is one of divergence associated with some sursumvergence."

From the standpoint of orbital structure alone, the eyes should assume at all times a position of divergence of the visual lines. The fact that they never do this in the absence of pathologic change, except in deep sleep or narcosis, simply means that the reason for the lack of divergence is the existence of some antagonistic force which cannot be explained on structural grounds alone.

Physiologic. The first question that must be asked is this: Are the extraocular muscles strong enough to produce true

divergence of the visual lines (or convergence either, for that matter), *if properly innervated?* Lancaster¹⁰ has answered this question quite definitely. He has shown that each of the extraocular muscles should have a maximum strength of 750 to 1,000 gm., provided all the fibers contract at once. The amplitude of excursion—the amount of shortening that can occur when a muscle contracts—is about one half to one third of its length; that is, a muscle 40 mm. long could shorten 13 mm. or more. In the eye, a 13-mm. shortening of one muscle would result in a rotation of over 65 degrees of arc, yet the eyes are capable of only 40 to 50 degrees of rotation from the primary position.

Lancaster¹⁰ and Kennelly³⁹ estimated the force required to rotate the eyeball as being 1.00 to 1.75 gm., neglecting friction, and estimating the weight of the eye as 8.0 gm., and its size as 24 mm. in diameter. Even when making liberal allowance for the extra weight and drag of the optic and ciliary nerves, the arteries and vortex veins, the conjunctiva, fascia, and fat, they believed it reasonable to assume that a pull of 5.0 gm. is entirely sufficient to move the eye at its observed velocity. This means that the extraocular muscles are powerful enough, *if properly innervated*, to exert a pull 100 times the amount needed to move the eye. Probably less than 5 percent of the fibers are made to contract at any one time. If proper innervation is available from either a convergence or a divergence center, certainly the extraocular muscles are strong enough many times over to produce adequate movements of divergence and convergence. But during consciousness the eyes never diverge in the absence of any pathologic lesion. It is obvious that at no time when binocular vision is in use can the visual axes diverge.¹⁴ From the standpoint of function, therefore,

there is no necessity to assume a center for pure divergence.

What then are the tenets of the elasticity theory? In the absence of any innervation (as in deep sleep or narcosis), there is divergence of the visual lines which is solely the result of the elastic pull of the orbital structure. When consciousness supervenes and the eyes are opened, the convergence innervation arising from the convergence center is called into play and fixation is accomplished. Varying amounts of convergence innervation result in varying degrees of convergence; when it is desired to shift the gaze from a near object to a remote one, the degree of convergence is lessened by a proportionate decrease in the convergence innervation. Since the elastic divergent pull of the orbital structure is constantly present, a decrease of the convergence innervation allows the elastic divergent pull to act passively but nevertheless effectively, and the visual lines are thus made to converge less, fixating the more remote object. This is the elasticity theory and it is not a new one. Berry⁴⁰ stated that divergence was essentially an inhibition of convergence. Stutterheim⁴¹ called the anatomic position of rest one of passive divergence due to elasticity, with the eye held there by anatomic structures; he said that the extrinsic muscles acted as tensors—"... they act by contraction in the direction away from the primary position" (his "primary position" is the same as the anatomic position of rest of other writers). He continues "... *in the direction towards the primary position, they act by inhibition alone*" (the italics are his).

DISCUSSION

For purposes of clarity, it should be restated that two concepts of divergence exist. One might be considered "true" divergence, a condition wherein the visual

lines of the two eyes actually diverge and for that reason would cross each other only if prolonged backward through the eyeballs. The other concept of divergence (Duane's) is called negative convergence by many and is a process wherein the visual lines of the two eyes are made to converge less. The crux of the matter lies, of course, in the mechanism behind the production of the two types of divergence.

Anatomically, in the absence of any innervation at all, the two eyes should diverge from each other by virtue of the elastic pull of the orbital structures. Physiologically, the extraocular muscles possess many times enough power to produce either divergence, convergence, or any conjugate movement if properly innervated. Yet, in the conscious state in the absence of a pathologic process, true voluntary divergence has never been proved to exist. The elastic divergent tendencies of the orbital structure must be combated by some force, since true divergence does not occur in consciousness. The force involved is obviously that of convergence innervation from a convergence center, which has been demonstrated both anatomically and physiologically by Bender and Weinstein.³ Assume for the moment that there is no divergence center and no active divergence. It still seems important to elicit an antagonist for the convergence innervation known to exist.

The "force" of convergence pulling against the "spring" of elasticity inherent in the orbital structures and tending toward divergence satisfies the requirement of an antagonist for the convergence innervation. If this assumption is tentatively accepted as correct, an analogy to a spring scale is quite striking. If no pull (force) is exerted on a spring scale, it will read zero; similarly, if no convergent pull, resulting from convergence innervation of the extraocular muscles, is

exerted on the eyeballs, they diverge in what might be called the zero position (as they do in deep sleep or narcosis). When pull is exerted on a spring scale, the reading varies from zero depending upon the force of the pull and continues to stay away from zero until the pull is released; it then returns to zero (the resting position of the spring scale). If the pull resulting from convergence innervation is exerted on the eyeballs via the extraocular muscles, they leave their divergent position (zero position) by an amount proportional to the convergent force exerted and stay away from that position until the pull is removed (in deep sleep or narcosis); they then return to their zero position of divergence. This theory of the production of divergence by elasticity of the orbital structures alone is not new,^{40,41} and Bruce² referred to it as "... elasticity in divergence." The evidence in support of the elasticity theory of divergence comes from several sources.

1. When an eye is blinded by trauma, exotropia is an almost invariable result. The passive elastic divergent effect of the orbital structure is being exerted. Nevertheless, even with fusion completely disrupted, the fixation reflex (monocular)¹² will cause the angle of squint to vary from time to time as the convergence innervation varies. This is a commonly observed clinical phenomenon.

2. Bell's phenomenon, probably for protection of the eyes during sleep, also indicates strongly that when fusion is completely disrupted and the monocular-fixation reflex is obliterated as well, any convergence innervation is at a minimum and elastic divergence occurs, in addition to elevation of the globes.

3. Bielschowsky¹¹ cites a case of a patient with complete bilateral paralysis of the sixth cranial nerves who habitually kept his chin pressed against his chest. This position (eyes elevated in relation to

their respective orbits) enabled the patient to secure binocular single vision because elastic divergence of the orbital structure could more easily act in this position in spite of complete sixth-cranial-nerve paralysis, which meant, in turn, complete loss of any possible divergence innervation from a divergence center.

4. Although admitting that "divergence paralysis" might easily be convergence spasm, Bielschowsky¹¹ nevertheless lists seven characteristic findings in the former entity. Of the seven, only one (the fourth) appears to offer any difficulty of explanation on the basis of convergence spasm. "... when an object is brought nearer to the eyes than the point at which no diplopia exists, insufficient convergence may produce a crossed diplopia." How could insufficient convergence be present if there is a convergence spasm? Bielschowsky himself affords the answer "... the idea of convergence spasm superimposed upon, or together with, a convergence weakness is by no means unusual—a peculiarity seen especially in neurasthenia, an important characteristic of which is the combination of increased irritability and abnormal exhaustibility."

5. In total ophthalmoplegia, the eyes rarely look straight ahead in a parallel direction but usually diverge slightly, and very exceptionally converge.⁴²

6. Exophoria is the almost invariable finding after prolonged occlusion.¹⁴

7. Characteristic of cases of "divergence paralysis" is the fact that they suddenly develop into bilateral sixth-cranial-nerve paralyses.¹¹ Bruce's² reasoning indicates the probable location of a divergence center as the midline. The sixth-cranial-nerve nuclei, however, are not in the midline.^{3, 43, 44, 45} Bielschowsky¹¹ offers the explanation that in "divergence paralysis," the lesion is supranuclear in location, then spreads to involve the sixth-cranial-nerve nuclei, and thus pro-

duces bilateral sixth-nerve paralysis. If Bielschowsky's explanation is correct, the divergence center could not lie in the midline; if it did, it would be an amazing coincidence that a supranuclear lesion of the divergence center would spread laterally with such symmetry as to involve both sixth-cranial-nerve nuclei simultaneously! Yet all Bruce's work indicates that if a divergence center exists, it probably lies in the midline.

8. If divergence and convergence are separate entities, produced by separate centers, then exophoria and esophoria should also be separate and independent of each other. It is agreed that the more successful a test is in disrupting fusion, the more heterophoria that test will uncover. The addition of screening to the Maddox-rod test provides greater disruption of fusion than the use of the Maddox rod alone. The addition of screening to the Maddox-rod test, therefore, should elicit more esophoria or more exophoria, whichever the case might be, than the test without screening. Instead, the addition of screening and the consequent greater disruption of fusion elicits more esophoria and less exophoria. Exophoria and esophoria appear not as separate entities but rather are interdependent, one upon the other, and actually represent varying degrees of the same thing. This is understandable only when a convergence center exists alone, and there is no divergence center.

Haessler³⁵ has wisely cautioned that the matter is a biologic problem. In biology the emphasis is necessarily on empiric observation, and explanatory patterns must be adopted cautiously and tentatively, with full realization that they

must be constantly revised as fresh evidence is elicited. Until a divergence center is demonstrated anatomically, or until more convincing evidence of its existence is forthcoming, the elasticity theory of divergence as a passive antagonist to active convergence seems to offer a satisfactory explanation of all observed phenomena.

SUMMARY

Although the existence of a center in the brain for ocular convergence is well established, the evidence for the existence of a separate center for ocular divergence is not convincing. The arguments for a divergence center fall into three subdivisions: (1) phylogenetic—divergence must have developed as an antagonist of convergence; (2) physiologic—divergence is an active process and hence must have its own innervational center; and (3) pathologic—since "divergence paralysis" is recognized, it must be caused by a lesion in the divergence center.

When the Maddox-rod test of heterophoria is performed with and without screening and the results compared statistically, the addition of screening is found to elicit more esophoria and less exophoria. This is construed as evidence for a single vergence center (convergence), since exophoria and esophoria behave not as independent entities but rather as varying degrees of the same entity.

The theory of passive divergence due to elasticity of the orbital structure is reviewed and further clinical evidence is put forward to substantiate it. It would thus seem that the majority of phenomena can be adequately explained on the basis of a single vergence center in the brain (a convergence center).

PERIARTERITIS NODOSA WITH INVOLVEMENT OF THE CHOROIDAL AND RETINAL ARTERIES*

J. GOLDSMITH, MAJOR (MC), A.U.S.

New York

The following case of periarteritis nodosa is being reported because the diagnosis was made during life, after ophthalmoscopic examination, in conjunction with the clinical history and the physical findings. A fusiform aneurysm of the inferior temporal artery of the fundus of the right eye was the most important finding and aided greatly in establishing the diagnosis of periarteritis nodosa. This will be discussed more fully in a later section.

The detection of this strange malady has seldom been made during life and then it has been more or less accidental. Because of its protean character and bizarre manifestations, it can simulate any one of the many ordinary clinical entities. The abdominal distress of which so many of the patients complain is due to vascular involvement of the various organs within the peritoneal cavity. Several exploratory laparotomies have been performed for just such surgical emergencies and the findings obtained revealed the characteristic pathologic processes of periarteritis nodosa.¹

This disease entity was first accurately described by Kussmaul and Maier² in 1866 as a definite inflammatory disease involving the medium and small arteries. Since then, this relatively rare disease has been reported at intervals until a fairly voluminous literature has accumulated on the subject, containing reports of extremely varied clinical manifestations.

The appearance of gross aneurysmal dilatations of the arteries to which the

syndrome owes its name is not the essential characteristic.³ The pathologic changes consist of a nonsuppurative inflammation beginning in the outer portion of the medium and small arteries and are accompanied by a fibrinoid degeneration of the media which secondarily involves the intima. The primary locus of origin of the necrotizing process in the arteries has not been established. There is extensive vascular and perivascular infiltration with polymorphonuclear neutrophils, eosinophils, and to a lesser extent with lymphocytes. The smaller vessels become occluded if the process extends to the intima. Exudation, which is followed later by necrosis, results in the formation of aneurysm and thrombosis. Only rarely has marked involvement of the veins been noted.⁴ The etiologic factor of periarteritis nodosa has long been veiled in obscurity. The streptococcus has been considered more frequently than any other organism, although syphilis has been offered by several writers as a strong possibility. The poor response to anti-luetic treatment and the inability to find the spirochete dismiss syphilis as a possible cause. Other concepts which have received wide speculation are: a filterable virus,⁵ a variety of different infections, disease of the central nervous system, and toxic injuries to the vessel wall. Only recently has there been any suggestive experimental evidence offered along the lines of hypersensitivity as a possible factor in the causation of this necrotizing vascular disease. Rich and Gregory⁶ have produced in rabbits, by experimental means, pathologic lesions resembling

* Read before the medical staff, Battey General Hospital, Rome, Georgia, May 21, 1945.

those of periarteritis nodosa in man, as a result of an anaphylactic type of hypersensitivity following foreign sera and sulfonamide administration.

This disease has no age incidence since cases have been reported in infancy and in the aged. Fifty percent of the cases occurred between the ages of 20 and 40 years.⁷

The clinical course consists usually of a chronic sepsis, marked emaciation, weakness, anemia, and a long-continued, low-grade, septic temperature curve. This disease is characterized by a multiplicity of clinical and laboratory findings, since the arterial system of a set of organs is invariably involved. As the necrotizing process subsides in one organ, it may manifest itself in another, thus demonstrating that the disease is punctuated with remissions and relapses. The preceding mechanism can thus account for the so-called healed stages of periarteritis nodosa.⁸ Since there is some tendency to remission and even apparent recovery in the severe and recognized cases, it is possible that many mild cases exist and go on to spontaneous recovery unrecognized. One can render the bewildering symptomatology of the disease less intricate by assuming the presence of an infectious process which, in addition to producing general disturbances such as fever, tachycardia, prostration, cutaneous eruptions, and leucocytosis, causes symptoms based on circulatory disturbances in the systems or regions affected.⁹

The treatment is principally symptomatic. Repeated small blood transfusions, liver, and iron have been employed to combat the severe anemia. Antiluetic therapy is of highly questionable value.

REPORT OF A CASE

A corporal in the United States Army, aged 43 years, developed an acute gonorrhea on March 2, 1943, in Natal, Brazil.

He was sent to the infirmary at Natal, and, after receiving 100 gm. of sulfathiazole was returned to duty as cured on April 2, 1943. One day, after his return to duty, the discharge reappeared, and he was given 100 gm. of sulfadiazine, with improvement. The urethral discharge, which recurred on three other occasions during a three-months' period, necessitated further hospitalization. He received an additional 32 gm. of sulfathiazole and 100,000 units of penicillin.

In view of the failure of this patient's urethral discharge to respond to the sulfonamides (total 232 grams) and penicillin therapy, he was evacuated to the United States, on October 21, 1943, and was admitted to the AAF Regional Station Hospital No. 1, Coral Gables, Florida. At this time, the patient complained of generalized muscular aching, weakness, a loss of 30 pounds within two-months, a daily fever over a period of one month, pain and swelling in the left ankle, and a return of nausea following meals, of which he had been complaining for several weeks. He also had had pain in the shoulder girdle which radiated to both arms and hands, as well as numbness and loss of grip in both hands for two months. The pain persisted in both upper extremities and then subsided, to be followed by paresthesia involving all the fingers of the left hand, and the thumb, index, and middle fingers of the right hand.

The patient was admitted to the Ream General Hospital on November 13, 1943, complaining chiefly of weakness, numbness, and paresthesia in all four extremities. He also had frequency of urination and nocturia. He was originally admitted to the Surgical Service, but in view of the extensive peripheral neuritis was transferred to the Medical Service. The family history was irrelevant. There was no history of any serious diseases prior to his present illness.

Physical findings. The patient weighed 131 pounds (59.5 kg.). He was pale and poorly nourished. The eyes, ears, nose, and throat were essentially normal. The heart and lungs were normal. There was slight swelling and tenderness of the left ankle, and also generalized depression of the deep reflexes, with weakness of all the extremities. The muscle tenderness was severe. The epicritic sensibilities were markedly diminished to almost absent in the distal portions of both the upper and lower extremities. The cranial nerves were intact. The blood pressure, which had always been 110 systolic and 70 diastolic during the past year, was 130 systolic and 80 diastolic at the time of admission.

On November 15, 1943, red blood cells numbered 3,320,000 with 59 percent hemoglobin. White blood cells numbered 7,250 with eosinophils 4 percent. Previously, on July 14, 1943, the blood revealed a 10-percent eosinophilia. The sedimentation rate was 27 mm. The blood Kahn reaction was negative. This test, which was performed on three other occasions, was always reported as negative. The urine was negative for albumin, but microscopic examination revealed the presence of a few pus cells. Previous urine specimens at other hospitals had been essentially normal, except for pus cells, which were present in moderate degree, during the gonorrheal exacerbations. Several X-ray films of the chest were negative. The feces was negative for ova and parasites. Cholesterol was 168 mg. per 100 c.c. of blood. The total blood proteins were 6.2 percent. The nonprotein nitrogen was 24 mg., creatinin, 1.4 mg., and sugar, 66 mg. Urethral smears were negative for gonococci at the time of admission, although the 194th Station Hospital reported gram-negative extracellular diplococci, with many pus cells, on July 12, 1943. Lumbar puncture on two occasions revealed a normal spinal fluid under nor-

mal pressure. *Staphylococcus albus* was grown from a urine culture.

The patient was placed on a high caloric, soft diet with large doses of all the vitamins, especially thiamin chloride and B-complex. Intramuscular liver injections were administered as well as iron and general supportive treatment. In addition, the patient was given physiotherapy daily for his peripheral neuritis in an effort to maintain muscle tone. The patient improved initially, but subsequently went on to several remissions and relapses. On November 26, 1943, the blood showed white cells, 10,200 with eosinophils 6 percent. Urinalyses during January and February, 1944, showed a moderate trace of albumin, many bacteria, few finely granular casts and an average of two pus cells and one red cell, microscopically. Repeated urethral smears were negative for gonococci. Nausea following meals was a constant complaint, and on December 6, 1943, a gastrointestinal series and a gastric analysis were performed, revealing no evidence of organic pathologic change. The patient complained of frequency of urination and nocturia, but the diagnosis of pyelonephritis or cystitis could not be substantiated. Lumbar puncture on January 4, 1944, showed a normal spinal fluid under normal pressure.

Ocular examination. On January 31, 1944, the patient stated that his vision had become blurred for the first time. Eye consultation on February 1, 1944, revealed the following findings: Vision, O.D. 20/200, O.S. 20/100 uncorrected; O.D. 20/50—3 with +2.00D. sph. \approx —0.50D. cyl. ax. 90°; O.S. 20/50—1 with +2.00D. sph. \approx —0.75D. cyl. ax. 90°. Associated parallel movements were full in all cardinal directions. Absolute central scotomas were present in both eyes, with bilateral enlargement of the blind spot (figs. 1 and 2). The pupils

were round and regular and reacted sluggishly to light and fairly to accommodation. Intraocular pressure was within normal limits by finger palpation. The cornea, lens, and vitreous were clear in both eyes.

Fundus, O.D. The disc margins were completely blurred, and the color of the disc very hyperemic (fig. 3). The disc was elevated about 0.5 to 1 diopter. The details of the cup were barely discernible. There were six fresh linear hemorrhages

few hemorrhages and exudates were seen in the periphery.

Fundus, O.S. The disc margins were completely blurred and the disc was elevated about 0.5 to 1 diopter, and markedly hyperemic (fig. 4). Four linear hemorrhages were seen on the summit of the disc. Very few hemorrhages were seen in the retina. A number of soft exudates surrounded the periphery of the elevated papilla. There were no aneurysmal dilations. The arterial changes were similar

Figs. 1 and 2 (Goldsmith). Visual fields on January 31, 1944. Fig. 1, O.D. Enlarged blind spot; absolute central scotomas for red and white. Vision 20/200 correctable to 20/50-3. Targets, white and red 2/330 and 5/330. --- = red.

Fig. 2, O.S. Enlarged blind spot; absolute central scotomas for red and white (smaller than in O.D.). Vision 20/100 correctable to 20/50-1. Targets as in figure 1.

and several faint exudates scattered in the superficial loose tissue of the elevated papilla. The periphery of the disc was striated radially and blended imperceptibly with the flat retina. Several fresh linear and round hemorrhages were studded through the posterior pole of the fundus. The exudates were soft and blended with the surrounding retina. The arterial tree showed moderate damage. About one disc diameter away, along the course of the inferior temporal artery, a fusiform type of aneurysmal dilatation replaced the artery for a distance slightly less than one disc diameter. The margins of the aneurysm were clearly delineated. The arteries showed moderate changes in caliber (probably angiospastic in origin) and in many places were obliterated so that one could barely make out the vessel walls. There was slight arteriovenous constriction. The veins appeared congested. Several of the linear hemorrhages were white-centered. The fovea was intact. A

to those seen in the right eye. The veins were congested, and the arteriovenous constriction appeared slight. The periphery was within normal limits.

Diagnosis: (1) Neuroretinitis, bilateral, with aneurysm of the right inferior temporal artery, due to periarteritis nodosa; (2) generalized periarteritis nodosa; (3) lupus erythematosus disseminatus.

It was suggested that the patient be given repeated, small blood transfusions to combat the severe secondary anemia. Several fresh hemorrhages and exudates were observed in both fundi on February 4, 1944. There had been no further increase in the elevation of either disc. It was suggested that a biopsy specimen be taken from muscle to rule out periarteritis nodosa. Repeated blood-pressure readings never exceeded 150 systolic and 100 diastolic. The patient had been running a febrile course, ranging between 98° and 102°F., over a period of four months.

Despite this, the patient's general condition appeared unchanged during this time. No fresh hemorrhages nor exudates were noted on February 12, 1944. No further elevation of the discs was observed. This was a case of bilateral optic neuritis and was not due to an expanding intracranial lesion. The patient had been constipated since admission. On February 15, 1944, a

male, with an estimated weight of 105 lbs. (47.7 kg.). The muscles showed moderate wasting. There was no urethral discharge.

The right pleural cavity was largely obliterated by diffuse adhesions. The lower lobes of both lungs were congested. Pulmonary vessels, large and medium bronchi showed no obstruction. The peri-

Figs. 3 and 4 (Goldsmith). Fig. 3, Fundus O.D. A, fusiform aneurysm of the inferior temporal artery; N, optic neuritis with 0.5 to 1 diopter elevation; H, hemorrhage, several white-centered; E, exudate; marked angiospasm of retinal arteries; slight arteriovenous constriction.

Fig. 4, Fundus O.S. N, optic neuritis associated with hemorrhages and exudates; V, veins congested; angiospastic retinal arteries.

second lumbar puncture was performed. The fluid was normal except for an early rise in the colloidal gold curve. The pressure was not increased. The patient suddenly developed nausea, vomiting, and stupor on February 16, 1944. This was followed by generalized convulsions and death. The patient was pronounced dead at 1850 hours (6:50 P.M.). No biopsy specimen had been taken from a muscle *intra vitam*.

Postmortem examination (Homer H. Hunt, Capt.). The body was that of a markedly emaciated middle-aged, white

cardium contained 50 c.c. of clear, straw-colored fluid. The right ventricle was soft and flaccid. No evidence of vegetations was present. The coronary vessels were soft and collapsed and showed no thrombi. The intima of the aorta had a slight yellowish discoloration. The thymus was atrophic. The capsule of the spleen was wrinkled and the parenchyma was soft, reddish brown, and scraped easily. The liver appeared normal. There were small grayish areas in the periadrenal, fatty tissues. The middle portion of the appendix was slightly constricted and hemorrhagic. There were depressed,

Fig. 5 (Goldsmith). Small artery in the epicardial fatty tissue demonstrating F, fibrinoid degeneration; intimal proliferation; L, leucocytic infiltration (polymorphonuclear neutrophils, lymphocytes, plasma cells, and eosinophils) into the adventitia, media, and intima; P, perivascular infiltration.

dark-red areas and recent small hemorrhages in the cortex near the upper pole of the left kidney; the right kidney was normal. The pelvis and ureter of both kidneys were normal. The right testicle was small and was yellowish on section. The brain and cord was normal grossly and on cut sections. The left middle ear showed a soft, glairy yellowish-brown material in the region of the medial mastoid cells. There were patches resembling old hemorrhage throughout the length of the petrous portion of the temporal bone.¹⁰

Microscopic examination. The arteries of all the viscera, especially those of the heart, kidneys, pancreas, appendix and liver, showed a focal periarteritis characterized by fibrinoid necrosis of the media with a tendency to aneurysmal formation. This inflammatory process was observed in different stages. Early stages were characterized by an abundant perivascular infiltration of lymphocytes, polymorphonuclear neutrophils, occasional plasma cells, and eosinophils. The infiltrate formed dense cuffs and extended into

the adventitia. The media appeared frayed, edematous, and was also infiltrated with leucocytes, as seen in one of the vessels in the epicardial fatty tissue (fig. 5). Later changes, as in the kidney, showed the media undergoing fibrinoid necrosis, usually involving the entire circumference of the vessel. The intima demonstrated proliferation of the endothelium as well as subendothelial proliferation of new connective tissue infiltrated with leucocytes. Following medial necrosis, aneurysmal formation by stretching of the necrotizing tissue was not unusual, and in one instance the aneurysmal dilatation of the pancreatic artery showed recent perforation with hemorrhage into the surrounding tissue (fig. 6). In some instances, as in the appendix, active inflammation was inconspicuous whereas the vessel wall showed very marked fibrous thickening of all coats, with organized occlusive thrombosis (fig. 7). The smaller arteries and veins as well as the arterioles and venules frequently showed perivascular infiltration of lymphocytes and polymorphonuclear neutrophils, although thrombosis was unusual (fig. 8).

Fig. 6 (Goldsmith). Large pancreatic artery. Marked necrotizing arteritis (N), with aneurysmal dilatation (D), and recent perforation at this point (P); the pancreatic acini, A, appear compressed and show early degenerative changes in several places.

A detailed description of additional changes in the kidney would not be amiss at this time (fig. 9). Section showed marked vascular changes in all stages as afore described; however, many vessels appeared essentially normal. For the most part the glomeruli appeared normally cellular and blood-filled. Here and there, in relation to the vascular damage, glomeruli showed degenerative changes varying from increased cellularity, ischemia, and crescent formation in the capsule to complete hyaline necrosis. Interstitial infiltration of lymphocytes and fewer polymorphonuclear neutrophils surrounded these areas. In areas throughout the pyramids, marked interstitial leucocytic infiltration was present with fibroblastic reaction and tubular degeneration. The parenchymal changes were incident to the vascular damage, previously described.

Microscopic diagnosis. Periarteritis nodosa, with involvement of the heart, spleen, kidneys, liver, lungs, and other viscera; peripheral neuritis, due to vascular involvement of the nerve sheaths and

Fig. 7 (Goldsmith). Appendicular artery. Healed stage. Active inflammation inconspicuous. The vessel wall shows very marked F, fibrous thickening of all the coats; T, organized occlusive thrombosis.

Fig. 8 (Goldsmith). Peripheral nerve, showing early changes of periarteritis nodosa in the smaller arteries of the sheath. Advanced changes also were seen. C, perivascular cuffing and mild adventitial infiltration with polymorphonuclear neutrophils, eosinophils, and occasional plasma cells.

trunks; occlusive appendicitis, due to involvement of the appendicular artery; right fibrinous pleuritis.

The right eye was forwarded to the Army Medical Museum, and on June 1, 1944 the following report was received: Gross. The cornea is slightly cloudy due to fixation. There are retinal opacities posteriorly and edema at the macula.

Microscopic. On one side there is elastosis of the conjunctiva, and granular deposits are seen in the outer corneal lamellae at the limbus (fig. 10). The iris

Fig. 9 (Goldsmith). Small renal artery. Moderately advanced stage. Media demonstrating fraying of smooth muscle fibers (F), edema (E), and fibrinoid necrosis; intimal and subendothelial hyperplasia (I) with incomplete thrombus formation (T); leucocytic infiltration (mainly lymphocytes) throughout the circumference of the vessel wall.

Fig. 10 (Goldsmith). Sagittal section, O.D. E, elevation of disc; retina partially detached by serous exudate; F, folding of retina in macular region; S, sclerotic changes in smaller orbital arteries.

appears somewhat edematous, with rarefaction of the cellular structure. There is slight vacuolization of its pigment epithelium. There are early degenerative changes in the cortical lens fibers. In the filtration angle, the iris root approximates the ligamentum pectinatum, without being actually adherent to it. The ciliary processes are edematous and somewhat hyalinized. There is serofibrinous and hemorrhagic detachment of the ciliary body and peripheral choroid. In the posterior choroid are focal areas of lymphocytic and large mononuclear cell infiltration around small arteries with greatly thickened walls which show hyalinization and fibrinoid

change. In these, the endothelial linings are somewhat proliferated and the lumina narrowed almost to the point of occlusion (figs. 11, 12). A number of the involved arteries show aneurysmal dilatations. The choroid is irregularly thickened by the inflammatory and vascular changes. The retina is partially detached, with serous exudate beneath it. It is folded in the macular region. Vascular changes in the retina are not marked, but hemorrhagic and serofibrinous exudates are present,

Fig. 11 (Goldsmith). Four choroidal arteries. A and D show early changes of periarteritis nodosa, fraying of the medial smooth-muscle fibers, and mild perivascular leucocytic infiltration; B, advanced stage, complete occlusive thrombosis; C, intimal and subendothelial proliferation with marked medial fibrinoid necrosis (F); choroidal thickening due to infiltration with many inflammatory cells.

particularly in the outer plexiform and nuclear layers (fig. 13). These are numerous posteriorly, especially in the macular region. There is some microcystic degeneration. The nerve head is somewhat edematous. The lamina cribrosa is not depressed. There are sclerotic changes in the smaller orbital arteries but without evidence of inflammation. Diagnosis: Periarteritis nodosa, choroid; papilledema; incipient cataract (Col. V. E. Ash, M.C., U.S.A., Curator).

COMMENT

Involvement of the retinal blood vessels

Fig. 12 (Goldsmith). Two choroidal arteries each demonstrating A, aneurysmal outpocketings; periadventitial and adventitial infiltration with lymphocytes, polymorphonuclear neutrophils, and occasional eosinophils and plasma cells; moderate fibrinoid necrosis (F), and endothelial proliferation with encroachment upon the lumen; N, marked necrotizing arteritis.

with the typical periarteritic nodules has been a very rare finding. In some 350 cases of periarteritis nodosa which have been collected and described in detail in the literature up to the present time, only four cases have been reported with histo-

Fig. 13 (Goldsmith). Retina partially detached by serous exudate; MD, microcystic degeneration; and S, serofibrinous exudate into the internuclear plexiform layer; proliferation and migration (M) of pigmentary epithelium (E).

logic evidence of retinal arterial pathologic lesions.

Müller,¹¹ in 1899, was the first observer to note this rare pathologic picture. He described changes similar to those found in the small vessels in the brain. All degrees of blood-vessel disease could be made out. The earliest changes, beginning with leucocytic infiltration into the adventitia, were followed by a fibrinous exudation into the media, accompanied by necrosis. A certain amount of endothelial proliferation was present as well as retinal edema in the vicinity of the lesion.

Involvement of the central retinal artery with periarteritis nodosa was reported by v. Herrenschwand¹² and Böck.¹³ King,¹⁴ in 1935, reported a case in which there was intense generalized infiltration of the retina with lymphocytes and plasma cells accentuated in the periarterial regions, while the normal structure of the vessel walls was obliterated and endothelial proliferation was marked. This case was also associated with a transitory papilledema and a recurrent subacute uveitis which eventually led to enucleation because of a severe secondary glaucoma.¹⁵

There was a striking tendency toward aneurysmal formation in the case described in this paper. This vascular complication seemed to be a residual finding in a number of the involved arteries. The production of an aneurysm in periarteritis nodosa is an acute process and becomes established within a few weeks. The arterial wall from the adventitia to the intima is involved in an acute degeneration and inflammation. The aneurysms found in this necrotizing, arterial disease, can assume a variety of shapes ranging from saccular to fusiform. The histologic section, prepared at the Army Medical Museum from the right eye in the present

case, did not pass through the aneurysmal dilatation of the inferior temporal artery. This was most unfortunate, but it is hoped that such sections will be available following the war.

The arterial changes of periarteritis nodosa in the choroidal layer have been more frequently described than those in the retinal circulation. The first to demonstrate these pathologic changes were Christeller,¹⁶ Goldstein and Wexler,¹⁷ and Helpert and Trubek,¹⁸ in proved cases of endocarditis with multiple emboli. The last-named authors noted isolated, necrotizing lesions of the smaller arteries of the inner layer of the choroid in a patient who had gonorrheal urethritis.

King¹⁴ and v. Herrenschwand¹² also reported cases with the characteristic pathologic processes of periarteritis nodosa in the short ciliary arteries. A report of a young child with extensive ocular involvement was described in 1935 by Krahulick, Rosenthal, and Loughlin.¹⁹ This case demonstrated involvement of the anterior uvea with periarteritic nodules, as well as an episcleritis, orbital cellulitis, and arteritis of the choroidal vessels. An unusual case involving the vessels of the extraocular muscles without bulbar participation was described by Tertsch²⁰ in 1935.

In reviewing the literature, it was found, that no cases of periarteritis nodosa were ever diagnosed originally by fundusoscopic examination. This is readily conceivable, since approximately 81 percent of all the cases of periarteritis nodosa showed no pathologic changes of the fundi, whereas the remaining 19 percent invariably demonstrated, ophthalmoscopically the different stages of angiospastic retinitis.

The neuroretinitis, as described in the present case, was due principally to a severe toxic state. Superimposed on this

original fundus picture, one was able to observe ophthalmoscopically, incipient angiospastic arterial changes which were probably initiated by the mild hypertension due to slight renal damage. These organic changes in the kidney were due to the periarteritic, necrotizing process of some of the smaller renal arteries and were not primary in origin. It has been noted that renal involvement has occurred in 80 percent of all periarteritic cases.²¹ The clinical history, the ushering in of a mild hypertension late in the course of the disease, the moderate urinary findings, the normal blood chemistry, and the slight microscopic changes of the involved kidneys excluded the possibility of a malignant hypertension. The fatal termination was cerebral and not renal in character.

Goldstein and Wexler¹⁷ stated that on fundusoscopic examination the choroidal periarteritic nodules might reveal themselves in the retina as scattered whitish foci. Friedenwald and Rones²² observed rounded yellow elevations underneath the retina. They claimed that these elevations corresponded histologically to the periarteritic nodules in the choroid.

An interesting concept was recently postulated by Rich and Gregory⁶ on the basis of allergy. These authors stated that to continue administration of sulfonamides after a hypersensitive reaction has occurred may increase the danger of producing vascular damage such as is seen in periarteritis nodosa by prolonging the contact of the sensitized body with the offending antigen. The patient in this present report, who had received five courses of sulfonamides (a total of 232 grams) over a period of four months, might well fit into this category.

That the syndrome of periarteritis is usually superimposed on infectious or septic states has been known to many authors.^{18, 23, 24} These septic states act as the

prodromal illness and, after persisting for short intervals of time, are followed by a train of different symptoms which represent the initial necrotizing process of periarteritis nodosa. Thus we can readily conceive of the possibilities of initiating disease processes by creating hyperergic states within the septic host, by the indiscriminate and excessive use of such medicaments as the sulfonamides, the various sera and vaccines, and the many, newly arrived chemotherapeutic marvels.

Since the exact biochemical and immunologic reactions of these drugs are so complex and so little understood, great caution should be employed in their use in medicine. It is still unknown whether these drugs exercise deleterious or ameliorating effects on human tissue when administered over long periods of time. Continued experimentations along these lines are necessary before sound scientific facts can be established.

SUMMARY

1. Periarteritis nodosa with respect to its etiology, incidence, clinical course, diagnosis, prognosis, and treatment is briefly discussed.

2. A case of periarteritis nodosa is reported, with necropsy findings.

3. This syndrome was diagnosed for the first time *intra vitam*, by ophthalmoscopic observation in conjunction with physical findings and clinical course.

4. An aneurysmal dilatation of the fusiform type was observed in the fundus of the right eye involving the inferior temporal artery.

5. Other ocular findings of periarteritis nodosa are described.

6. The possibility of inducing hyperergic states within the human body by sulfonamides and sera administration is discussed.

FURTHER STUDIES ON THE USE OF FURMETHIDE IN THE TREATMENT OF GLAUCOMA*

ELLA UHLER OWENS, M.D., AND ALAN C. WOODS, M.D.

Baltimore, Maryland

In a previous paper one of us¹ (E. U. O.) has called attention to the favorable effect of furmethide in the treatment of primary glaucoma. The chemical relation of furmethide (furfuryl-trimethyl ammonium iodide) to other choline derivatives with parasympathomimetic action was discussed and its ocular pharmacology reviewed. Furmethide was found to be effective in reducing the intraocular pressure in primary glaucoma, both congestive and noncongestive. A 10-percent solution of furmethide appeared to be preferable to the synergistic use of a 20-percent solution of mecholyl and a 5-percent solution of prostigmine in the treatment of late cases of primary glaucoma.

Since the time of the first report our experiences with this miotic have been considerably amplified. It has been used in a large number of out-patients and in 65 additional hospital patients in the Wilmer Institute. The records of the out-patients are in many instances incomplete and therefore impossible of exact analysis. However, the same highly favorable action and absence of untoward reactions were noted in both groups. In this paper we are reporting the hospital cases only. These 65 cases together with the 41 cases previously reported give a total of 106 cases for analysis. The immediate reason for this further report is that the high therapeutic value of this drug and its freedom from toxic or local irritative reactions do not appear to be widely known among ophthalmologists, and there is some dan-

ger that the drug may not become available commercially.

TREATMENT OF PRIMARY GLAUCOMA

As is evident from the tables, furmethide was found to be equally efficacious in the congestive and noncongestive glaucomas. They are therefore reported together. The 65 cases in this analysis are those of patients with primary glaucoma whose intraocular pressure before therapy exceeded 40 mm. Hg (Schiotz). All of these patients were admitted to the wards of the hospital. One drop of a 10-percent solution of furmethide was instilled into the conjunctival sac every 15 minutes for two hours, then every three hours until the ocular tension was reduced to normal or until an operation was performed. The results are summarized in table 1. In the primary group, as a whole, furmethide reduced the tension to 35 mm. or less in 77 percent of the patients.

Tension before therapy was begun was over 55 mm. in 62 percent of the patients, and between 40 and 55 mm. in 38 percent. The tension was reduced to 35 mm. or less in 75 percent of the patients whose initial tension was over 55 mm. and in 80 percent of the patients whose initial tension was between 40 and 55 mm.

Early and late cases. The patients can also be divided into two groups; namely, those with early or late glaucoma. Early cases of glaucoma are arbitrarily considered to be those in which the field defect was less than 30 degrees in any meridian and the blind spot not enlarged more than 10 degrees in any diameter. All

TABLE 1
RESULTS OF FURMETHIDE THERAPY OF PRIMARY GLAUCOMA

Type of Glaucoma	Number of Cases	Tension Post Drug		
		25 mm. or less percent	26-35 mm. percent	36 mm. + percent
Congestive	41	46	29	25
Noncongestive	24	29	50	21
Total	65	40	37	23

other cases are classified as late. According to this classification 30 percent of the cases were early, 70 percent late. The tension was reduced to 35 mm. or less in 79 percent of the early cases and in 67 percent of the late cases.

Previous use of miotics. Forty percent of the patients had been on other miotics before furmethide was started. Usually these patients had been given a 2-percent solution of pilocarpine administered 3 to 4 times daily, with or without eserine ointment at night. Occasionally a 0.25-percent solution of eserine had been used 3 to 4 times a day, in one patient resulting in a severe eserine conjunctivitis. The tension was reduced to 35 mm. or less in 76 per-

cent of these patients as compared with a similar reduction of tension in 78 percent of the patients who had received no miotic therapy before furmethide was begun. In short, the drug was equally efficacious in patients in whom other miotics had failed.

TREATMENT OF SECONDARY GLAUCOMA

The use of furmethide was studied in a group of 41 patients with secondary glaucoma whose intraocular pressure before therapy was higher than 40 mm. Hg (Schiotz). The method of treatment was the same as in the treatment of patients with primary glaucoma. All of the patients were admitted to the wards of the hospital. The results of therapy are sum-

TABLE 2
RESULTS OF FURMETHIDE THERAPY OF SECONDARY GLAUCOMA

Type of Glaucoma	Number of Cases	Tension Post Drug		
		25 mm. or less percent	26-35 mm. percent	36 mm. + percent
Secondary to intracapsular cataract extraction	5	60	40	0
Secondary to extracapsular cataract extraction	6	17	33	50
Secondary to uveitis	15	27	13	60
Secondary to trauma	4	50	25	25
Secondary to aniridia	2	100	0	0
Secondary to venous thrombosis	9	0	0	100
Total	41	29	17	54
Total excluding venous thrombosis	32	37	22	41

marized in table 2. Furmethide had no effect on nine patients with glaucoma secondary to venous thrombosis. The tension was reduced to 35 mm. or less in 59 percent of the other cases of secondary glaucoma.

Untoward reactions. A possible systemic reaction to furmethide occurred in only one of the 106 patients treated with this drug. It consisted of moderately se-

SUMMARY

The results of furmethide therapy were studied in 106 patients with glaucoma whose intraocular tension before therapy exceeded 40 mm. Hg (Schiotz). Sixty-five of the patients had primary glaucoma, 41 had secondary glaucoma. All of the patients were admitted to the wards of the hospital. Furmethide reduced the tension to 35 mm. or less in 77 percent of

TABLE 3

COMPARISON OF THE FAVORABLE EFFECT OF TREATMENT WITH FURMETHIDE AND WITH MECHOLYL AND PROSTIGMINE ON VARIOUS STAGES OF PRIMARY GLAUCOMA: PERCENTAGE REDUCTION OF TENSION TO 35 MM. OR LESS

Treatment	Initial Tension over 55 mm. (S) percent	Initial Tension under 55 mm. (S) percent	Late Cases percent	Early Cases percent	Previous Use of Other Miotics percent	No Previous Use of Other Miotics percent	Total percent
Furmethide	75	80	67	79	76	78	77
Mecholyl and Prostigmine	54	75	41	92	44	77	58

* Statistically significant difference in percentage $d/\sqrt{d} > 2.0$.

vere perspiration, salivation, and lacrimation of brief duration, appearing 12 hours after the first administration of the drug. No local reactions occurred. None of the patients developed a local sensitivity to the drug.

FURTHER COMPARISON OF FURMETHIDE WITH MECHOLYL AND PROSTIGMINE

The data previously reported, on the 43 cases treated with mecholyl and prostigmine, may be compared with the data on the new total of 65 cases of primary glaucoma treated with furmethide. The results are summarized in table 3.

These figures substantiate the previously reported conclusion that furmethide is definitely preferable in late cases. In addition, furmethide was more effective than mecholyl and prostigmine in those cases in which the previous use of other miotics had failed.

the patients with primary glaucoma and in 59 percent of the patients with secondary glaucoma. A possible systemic reaction occurred in only one patient. No local reactions were noted, and none of the patients developed a local sensitivity to the drug. Additional experience with a large number of out-patients whose records are not sufficiently complete for statistical study is in accord with these results. The use of furmethide in the treatment of 65 patients with primary glaucoma compares favorably with the previously reported results on the use of mecholyl and prostigmine.

CONCLUSIONS

1. Furmethide is a valuable drug in the treatment of primary glaucoma, especially in the severer cases.
2. A 10-percent solution of furmethide

is more effective than the synergistic use of a 20-percent solution of mecholyl and a 5-percent solution of prostigmine in late cases of primary glaucoma, and in those cases of primary glaucoma in which the

previous use of other miotics has failed.

3. Systemic reactions to furmethide are rare. No evidence of local sensitivity or local irritation to the drug has been noted.

ORAL PENICILLIN IN OCULAR INFLAMMATIONS*

P. J. LEINFELDER, M.D., AND W. D. PAUL, M.D.

Iowa City, Iowa

Many patients with acute inflammatory diseases of the eye and adnexa would be benefited by the administration of penicillin, yet the nature of the local disease is not of sufficient severity to warrant the hospitalization necessary for intramuscular injections. To circumvent this disadvantage local application has been utilized with some success, but it is recognized that application of an ointment may be difficult for the patient, and the blurring of vision subsequent to administration is annoying. The use of solutions is helpful, but the rapid deterioration of the medication when in contact with moisture lessens its successful and easy employment. Oral administration overcomes all these difficulties and allows the patient to carry on his customary duties without interference.

The excellent results obtained by Paul *et al.*¹ in oral administration of penicillin in combination with aluminum dihydroxy aminoacetate† (glycillin) prompted us to utilize this method for treatment of inflammations of the eye. The results in a

series of 15 cases which includes acute conjunctivitis, blepharoconjunctivitis, hordeolum externum and internum, and uveitis are outlined in table 1. The response in each case was similar to what could be expected from intramuscular injections.

It is recognized that the series here presented does not constitute a large number of cases, but the rapid and in many instances spectacular results prompted publication. Unfortunately, the cultures in all cases were not positive for pathogenic organisms, but each case treated was of sufficient severity that clinically a positive culture was expected.

In most instances where treatment was successful improvement had occurred within six hours after the administration of penicillin had been started, and in all cases there was definite subjective and objective healing after 24 hours. In the four cases of uveitis treated there was no evidence to show that the course of the inflammation was altered by the penicillin. In one case a skin rash developed which, according to the dermatologist, could have been due to the medication. The drug was stopped after 24 hours because of this, but improvement was noted in the blepharitis.

*From the Departments of Ophthalmology and Medicine, College of Medicine, State University of Iowa.

TABLE I

RESULTS FROM THE ORAL ADMINISTRATION OF PENICILLIN FOR
OCULAR INFLAMMATIONS

	Name	Age	Diagnosis	Duration	Daily Dosage	Days Treated	Culture	Outcome
1	B.R.	9	Multiple hordeoli & cellulitis lid	3 days	16,000 u., q. 1 h. 10 X	3	—	Much improved in 24 hours; healed in 3 days
2	B.C.	57	Acute catarrhal conjunctivitis	1 day	20,000 u., q. 1 h. 5 X	2	No growth	Healed in 2 days
3	A.F.	48	Acute catarrhal conjunctivitis	1 day	20,000 u., q. 1 h. 6 X	3	No growth	Healed in 3 days
4	F.L.	81	Acute catarrhal conj. (Postop.)	1 day	20,000 u., q. 1 h. 6 X	2	D. pneumoniae. nonhem. Staph.	Healed in 2 days
5	G.H.	43	Subacute catarrhal conjunctivitis	1 day	16,000 u., q. 1 h. 5 X	1	Nonhem. Staph albus	Improved in 1 day; healed in 3 days
6	M.W.	35	Acute blepharo-conjunctivitis	2 wks.	20,000 u., q. 1 h. 10 hrs.	1	Nonhem. Staph albus	Healed in 2 days
7	J.F.	75	Chronic blepharo-conjunctivitis	6 mo.	20,000 u., q. 1 h. 6 X	2	No growth	Markedly improved in 2 days
8	A.L.	62	Chronic blepharo-conjunctivitis	10 mo.	20,000 u., q. 1 h. 6 X	9	Hem. Staph. albus	Marked improvement in 6 days; slow improvement thereafter
9	E.S.	40	Chronic uveitis	1½ yrs.	16,000 u., q. 1 h. 10 X	5	—	No improvement
10	G.S.	47	Acute uveitis	2 days	20,000 u., q. 1 h. 5 X	5	—	No improvement due to penicillin
11	A.W.	59	Acute uveitis	2 days	20,000 u., q. 1 h. 8 X	5	—	No improvement due to penicillin
12	W.T.	67	Chronic blepharo-conjunctivitis	Several years	16,000 u., q. 1 h. 8 X	2	No growth	No improvement
13	F.Z.	24	Chalazion	2 days	20,000 u., q. 1 h. 5 X	3	No growth	No improvement
14	B.S.	34	Acute blepharitis	1 day	16,000 u., q. 1 h. 6 X	1	—	Slight improvement in 24 hours, but developed acute dermatitis
15	I.B.	47	Hordeolum internum	2 days	16,000 u., q. 1 h. 6 X	2	Hem. Staph. aureus	Marked improvement in 6 hours; healed in 2 days

Penicillin in combination with aluminum dihydroxy aminoacetate was the only medication used for these patients. Dosage of penicillin varied, but it appears that 20,000 units, given every hour for five doses, is optimum. In more severe infec-

tions 200,000 units may be given on the first day, and in all cases the treatment on successive days is determined by the clinical results obtained by the preceding day's dosage.

SOME METHODS OF LID REPAIR AND RECONSTRUCTION

SIDNEY A. FOX, LT. COL. (MC), A.U.S.

Martinsburg, West Virginia

The present war has given to some of us the unique if unhappy opportunity of seeing a large amount of traumatic pathology of the eye and its adnexa. Injuries to lids and sockets are so varied and the destruction at times so great that one's ingenuity is often taxed to the utmost to repair the ravages of exploding shells, burning tanks, and flaming oil.

Yet one fact about war injuries of the lids has particularly struck me: Despite the different types of lethal agents and the variety of wounds seen, if the destruction has not been total—that is, if one or both lids have not been wholly destroyed—these injuries fall into readily classifiable categories not unlike those seen in civilian life.

This is no place for involved statistics. Let it suffice to state here that of the first 100 patients requiring plastic surgery seen on the Eye Service of this Hospital, 41 had injuries of the upper lid, 23 had injuries of the lower lid, and 36 had both lids injured. Of all these, 78 had or required enucleations. The lid notch or V-shaped incisura occurred almost twice as often as any other single lesion. Furthermore, it was found nine times more often in the upper lid than in the lower. Avulsion of the lower lid from the internal canthus with or without loss of lid substance was next in incidence. Cicatricial ectropion, paralytic ptosis, and cicatricial lagophthalmos were next in occurrence and about equal in incidence. Less common were the lunate (crescent shaped) deformities of the lid margin as well as ankyloblepharon and blepharophimosis. Not infrequently two or three of these lesions occurred simultaneously. Symblepharon was a concomitant of about half the cases. Sometimes this was of such

proportions as to require epithelial or mucous-membrane grafting to obtain an adequate socket for the reception of a prosthesis.

It should be stated that the incidence of cases given here has no relation whatever to the general incidence of ocular injuries in the present war. Of the latter I am not competent to speak. It should also be added that the injuries discussed in this series of contributions are only the more severe ones in patients who were sent back to this country for definitive treatment. Some of these men had to be treated for other injuries, more urgent, before plastic repair of the lids could be started. Hence, due to the exigencies of war, this could not be begun sometimes until 4 to 10 months after the injury had been incurred.

With so much material to see and work to do one cannot help but adopt certain favorites among the old techniques of lid repair and even try some new modifications. It is the purpose of this and subsequent communications to present some of the results of this work.

THE LID NOTCH

Many operations have been devised for the repair of the V-shaped lid notch. These need not be detailed to ophthalmologists. The best of them is Wheeler's¹ "halving" procedure or some modification of it. This still remains the classic procedure for most lid notches. With this method, however, some healthy skin must be sacrificed to obtain separate skin and tarsal suture lines which do not overlie each other. Furthermore, even with the most painstaking technique (at least in my hands) a small marginal hiatus is occasionally left which requires further

surgery. Also; in some of the cases seen here so much tissue had been lost that I was loathe to sacrifice any more. With a view toward circumventing these objections the following technique was devised:

The edges of the notch are freshened, and all scar tissue resected, care being taken to remove a minimum of healthy tissue. The lid in the region of the notch

sliding flap is freely mobilized by adequate dissection behind the conjunctiva, so that when it is drawn into place there will be no pull on the lid. A double-armed 3-0 black silk suture is passed through the edge of this flap from without inward (toward the conjunctiva) then through the horizontal edge of the rectangular dehiscence. The needles are passed through to the skin surface above or below the

Fig. 1 a, b, c, d (Fox). Technique used for repair of lid notch in cases 1 and 2.

is split into skin-muscle and tarso-conjunctival layers, and the skin-muscle layer freely mobilized by dissection. The fellow lid is split opposite the notch but only for a distance equal to the notch at the border (fig. 1 a). The notch in the tarso-conjunctiva is then converted into a rectangle by resection of the apex (fig. 1 b). From the opposite split lid a tongue of tarso-conjunctiva is fashioned which will fit snugly into the rectangle (fig. 1 b). This

notch (depending on its position in the upper or lower lid) and tied over a peg. If the notch is large, a suture of 4-0 plain catgut may be used on each side to help hold the flap in place (fig. 1 c). A double-armed 4-0 black silk suture is then threaded through another peg and the needles passed through the marginal edges of the skin-muscle notch from without inward. They are carried in front of the flap and then through the skin-

muscle layer of the uninjured lid, where they are brought out beyond the lash line and tied over a peg (fig. 1 c). Two or three additional interrupted black silk sutures are used to complete closure of the skin-muscle wound (fig. 1 d). A firm (not pressure) dressing is applied with bandage. This is changed on the fourth day for a patch. The sutures are removed on the sixth day. The eye is then dressed daily and can usually be left unpatched on the ninth or tenth day. The lids are separated after three weeks.

In case of an empty socket, a con-former should be inserted to assure

active treatment of his wounds and was admitted to this hospital on November 30, 1944. On January 11, 1945, repair of the right upper lid (fig. 2 a) was made, by means of the technique shown in figure 1. The result with permanent prosthesis is shown in figure 2 b.

Case 2. The soldier was injured on September 26, 1944, at Castro del Rio, Italy, when an enemy shell exploded near him and fragments entered his right eye. The eye was enucleated on September 28, 1944, at the 37th General Hospital, and on October 7, 1944, primary repair of his right upper lid was made. The patient

Fig. 2 a, b (Fox). Case 1, before and after repair of notch of right upper lid.

proper position of the pedicle flap. At first the arms of the marginal double-armed suture were crossed before insertion into the opposite lid was made, but this was found to be an unnecessary refinement and was subsequently discarded. When the notch is near either canthus, the incision splitting the lid is prolonged beyond the canthus to give sufficient mobility to the skin-muscle layer. No canthotomy is done.

CASE REPORTS

Two of 16 cases are reported.

Case 1. The soldier was injured on September 29, 1944, near Mancio, France, in a land-mine explosion. He sustained wounds of his right eye, right arm, and both legs. His right eye was enucleated the same day at the 11th Evacuation Hospital. He was shipped home for defini-

was returned to the United States and admitted to this hospital on December 2, 1944. On admission he had moderate notching and scarring of the right upper lid (fig. 3 a). On eversion of the lid, however, it was observed that the temporal half of the tarsus was involved in a mass of scar tissue all of which would have to be resected before a prosthesis could be inserted (fig. 3 b). On January 17, 1945, plastic repair of the lid was performed according to the technique outlined in figure 1. Figure 3 c shows the results three weeks after the repair and before the lids were separated. Figure 3 d shows the socket after repair. The final result with temporary prosthesis in place is shown in figure 3 e.

COMMENT

Case 1 (fig. 2 a, b) illustrates the type

of lid notch most commonly encountered: A somewhat large lesion more or less centrally placed. Case 2 (fig. 3) is deceptive. Tissue loss (fig. 3 a) was apparently minimal. As has been pointed out, however, a large portion of the upper tarso-conjunctiva had to be resected (fig. 3 b) before an adequate prosthesis could

of tissue has been minimal. In favor of it are the following facts: (1) No skin is resected. (2) The lid is not shortened. (3) The halving principle is retained. (4) Unless the notch is near a canthus no additional skin incisions are needed, and external scarring is consequently minimal. (5) Secondary surgical pro-

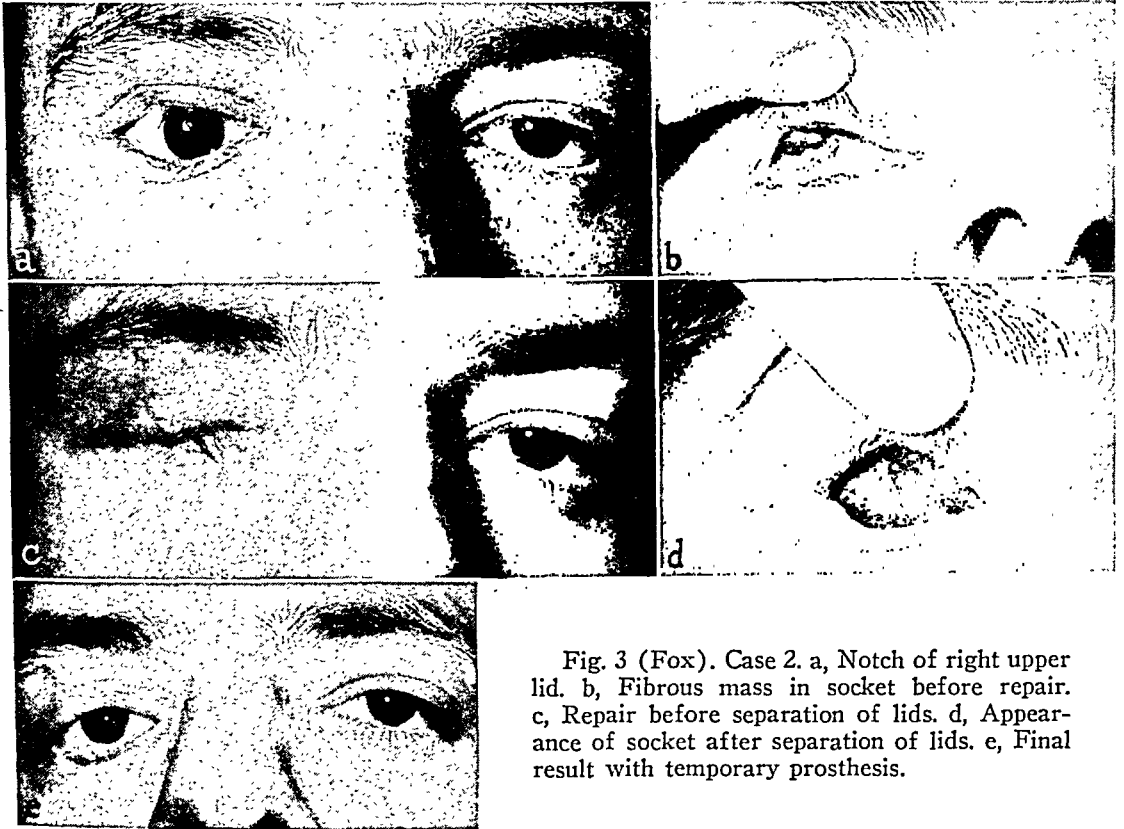

Fig. 3 (Fox). Case 2. a, Notch of right upper lid. b, Fibrous mass in socket before repair. c, Repair before separation of lids. d, Appearance of socket after separation of lids. e, Final result with temporary prosthesis.

be fitted (fig. 3 e). Had the usual halving repair been used, appreciable shortening of the lid would have resulted. The technique outlined in figure 1 would seem to be especially desirable in this type of case.

This procedure has now been used sufficiently often to permit of reasonably adequate evaluation. It is not suggested that it should supplant other procedures or that it is even applicable in all cases. Against it is the fact that it disturbs the anatomic relations of the normal opposing lid. It is also unnecessary where the loss

cedures are not needed unless lash grafting is done later.

LUNATE (CRESCENT-SHAPED) DEFORMITY OF THE LID MARGIN

Where lid injuries are seen in large numbers bizarre deformities are encountered. One of these, occurring not too commonly, is the lunate or crescent-shaped dehiscence of the lid margin. The loss of tissue is not extensive. The dehiscence is usually shallow, amounting to 6 or 8 mm. at its widest point. But most of the margin is involved and with it, of

course, the lash line. A good example of this type of lesion is seen in figure 5 a, b. Figure 6 a is even more characteristic but, unfortunately, the photograph is not too clear.

This injury, although not striking, requires as much planning and as painstaking a technique as do some of the more serious deformities. The following method has given satisfactory results:

two mobile flaps, one of tarso-conjunctiva and the other of skin-muscle, are created. These two flaps are pulled beyond the lid edge so that the point of deepest indentation of the deformity is on a level with the normal lid margin. The excess is resected (fig. 4 b). Three double-armed 4-0 black silk sutures are threaded through pegs and passed through both flaps near the lid margin from without

Fig. 4 a, b, c (Fox). Technique used for repair of crescentic lid-notch deformity in cases 3 and 4.

The affected portion of the lid margin is split into two layers, and the dissection carried sufficiently beyond the tarsus to obtain adequate mobilization. At the ends of the split, two vertical incisions are made in the tarso-conjunctival layer for a distance of 10 mm. Similar incisions are made in the skin-muscle layer but these are placed 2 mm. to the outside of the tarso-conjunctival incisions in order to obtain a halving effect (fig. 4 a). Thus

inward. One is centrally placed; the two lateral ones are inserted so as to straddle the verticle incisions (fig. 4 b). The edge of the opposing lid is freshened and the sutures are carried through this edge to come out beyond the lash line, where they are tied over pegs. One or two additional sutures are used to close the skin-muscle incisions. A conformer is inserted into the socket where no eye exists. A monocular dressing with bandage is ap-

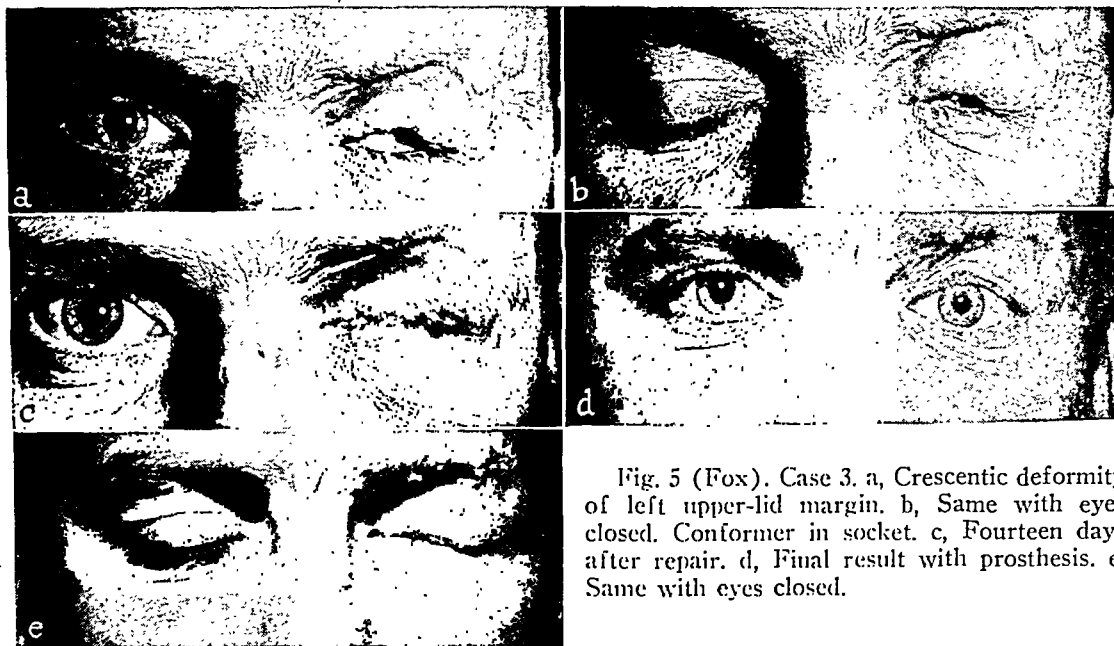

Fig. 5 (Fox). Case 3. a, Crescentic deformity of left upper-lid margin. b, Same with eyes closed. Conformer in socket. c, Fourteen days after repair. d, Final result with prosthesis. e, Same with eyes closed.

plied. The eye is redressed on the fifth, eighth, and tenth days, at which time the sutures are removed. The tarsorrhaphy may be opened in four to six weeks; or lash grafting may be done at this time.

CASE REPORTS

Case 3. The soldier was injured on August 6, 1944, on the Island of Guam by an enemy sniper bullet. He sustained wounds of the right hand, left eye, and left upper lid. The left eye was enucleated on August 9, 1944. The patient was returned to the United States and admitted to this hospital on November 1, 1944. On December 12, 1944, the left upper lid was repaired by means of the technique shown in figure 4. The result with eyes open and closed is shown in figure 5 d and e.

Case 4. The soldier was injured on July 7, 1944, near St. Lo, France, by enemy shell fragments. He sustained wounds of the back, right arm, right hand, left eye, and left lower lid. The left eye was enucleated on July 8, 1944. The patient was returned to the United States and admitted to this hospital on November 6, 1944. On November 24, 1944, plastic repair of the left lower lid was performed

according to the technique shown in figure 4. Figure 6 shows the lesion before and after repair.

COMMENT

This may seem like formidable surgery for a lid deformity which is not too strik-

Fig. 6 a (Fox). Case 4. Crescentic deformity of left lower-lid margin before surgery.

Fig. 6 b (Fox). Case 4. Same patient as in fig. 6 a after surgery.

ing. But attempts at simplifying the procedure have resulted in failure. Trials at pulling down a solid flap (without splitting) have not been successful. Also, omission of a surgical tarsorrhaphy have resulted in only partial correction with this technique. As can be seen from figures 5 and 6 a fair cosmetic and functional result is obtained with this type of repair. Lash grafting, performed in case 3 while the lids were united (fig. 5 c), was not successful. It was not done in case 4.

Other methods can be used for the repair of this type of deformity. As a matter of fact, another technique was evolved subsequently which will be reported in a later communication. How-

ever, the method herein outlined is adequate.

One final word: Time is the best ally of the plastic surgeon. With the passage of time scars diminish and discolorations fade. I have rarely seen a case following plastic repair which did not improve cosmetically as time went on. In the cases reported here the results are early ones. Once surgery is completed and the wound adequately healed, patients have to be sent away. Follow-up six months or a year later is not possible; the soldiers are either discharged or returned to duty. All the results reported in this series of communications should be judged with this in mind.

Newton D. Baker General Hospital.

REPORT OF A CASE OF IRIDOCYCLITIS ASSOCIATED WITH CHICKENPOX*

JOSEPH W. HALLETT, CAPT. (MC), A.U.S.

Drew Field, Tampa, Florida

A case of unilateral iridocyclitis which occurred during the course of an attack of varicella recently came under observation. The rarity of this combination is attested to by the paucity of published reports. Duke-Elder¹ refers to a case reported by Hutchinson in 1887 of a 21-month-old child with chickenpox who developed, on about the ninth day of the disease, a bilateral uveitis which resulted eventually in phthisis bulbi. No lesions of varicella were noted on the lids, conjunctiva, or cornea. To my knowledge no other cases of uveitis in association with varicella have been reported in the modern literature.

REPORT OF CASE

A 7-year-old white boy developed chickenpox on April 26, 1945. His temperature was moderately elevated for the first three days of his illness. The exanthem appeared diffusely over his body and face, and lesions were also noted on the mucous membrane of the oral cavity. On April 28th the patient's mother noticed that there was a slight discharge from his right eye and that the eye was red. He complained only of a frontal headache. The secretion from the eye disappeared within a day or two, without any local treatment, but the eye remained red. On May 2d he was referred by the pediatrician, Major A. O. Manske, for ophthalmologic consultation.

Examination revealed vision of 20/20 in each eye. The left eye was and remained completely normal. The palpebral conjunctiva of the right eye was mildly

injected, the bulbar conjunctiva more intensely so, and a moderate ciliary flush was noted. There was no secretion from the eye. The pupils were round and equal and reacted normally to stimulation. The tension to finger palpation was normal. A healing, crusted lesion on the right side of the bridge of the nose was the closest external manifestation of varicella to the eye. Upon biomicroscopic examination a moderate number of fine precipitates and a few small keratitic precipitates were discovered on the posterior corneal surface. A moderate number of cells freely floating in the thermal convection current of the aqueous and a well-marked aqueous flare were also noted. The iris and lens appeared normal; no synechiae were seen. The vitreous was clear and the fundus was normal.

A diagnosis of acute, iridocyclitis of the right eye was made. The application of hot wet packs to, and the instillation of 1-percent atropine sulfate solution in, the right eye three times daily were prescribed. An etiologic survey was then instituted.

Past medical history elicited the fact that the child had been an essentially normal, healthy infant. He had had an attack of cervical adenitis at two-and-one-half years of age and of mumps at five years. Urticaria, probably from grape juice, occurred once when he was six years of age. No recent immunization had been performed. The only previous ocular disease was an attack of "pink eye" two years prior to the presently reported episode.

Other than the subsiding exanthem and the ocular signs, physical examination revealed only a moderate cervical lymphad-

* From the Ophthalmologic Service of Lt. Col. Phillips Thygeson (MC), A.U.S.

enopathy. The tonsils were cryptic and of average size. The paranasal sinuses transilluminated clearly. The dentist exonerated the patient's teeth as possible foci of infection. The chest X ray was normal.

Urinalysis was normal. The blood Kahn, the tuberculin test, and the blood agglutination test for undulant fever were all negative. On May 4th erythrocytes numbered 3,820,000 and the leucocytes 5,200; the hemoglobin was 11.6 grams and the blood smear revealed 37 percent neutrophils, 56 percent lymphocytes, 1 percent monocytes, 5 percent eosinophiles, and 1 percent basophiles. On the same date the blood sedimentation rate was 40 mm. in the first hour.

Rapid clearing of all eye signs occurred, so that by May 7th the conjunctiva no longer appeared congested; the cornea and anterior chamber were completely cleared; the iris was normal; the pupil fully dilated, and the lens clear. Atropine was reduced to one instillation daily. Only a few small fading lesions of varicella remained on the body.

When next seen, on May 10th, a moderate bulbar conjunctival injection and ciliary flush were again noted. The pupil was about three fourths dilated. Numerous discrete, lardaceous keratitic precipitates were seen on the posterior corneal surface. A moderate number of floating cells in the anterior chamber and a faint aqueous flare reappeared. The tension to fingers was normal. Atropine instillations

were increased to three times daily and, upon the advice of the pediatrician, bed rest was ordered for the next few days. Medication for the moderate anemia was started. The sedimentation rate repeated on that day was 6 mm. in the first hour.

The patient was again seen on May 14th. The eye was then white, the pupil fully dilated, the keratitic precipitates completely gone, and the flare in the anterior chamber markedly diminished. On May 16th, except for the dilated pupil, the eye was clinically normal and has remained so to date.

Comment. In the absence of any other demonstrable cause it is probably reasonable to assume that this patient's iridocyclitis resulted from his coexisting chickenpox. Since, furthermore, the lids, conjunctiva, and cornea were free of vesicles or pustules, there must also be assumed a direct action upon the uvea by the virus, or its toxins, circulating in the blood stream. An unusual feature in the course of this case was the rapid appearance, after a period of improvement, of large lardaceous keratitic precipitates and their equally sudden disappearance. This type of precipitate is usually associated with long-standing severe cases of a granulomatous nature and typically does not exist so transiently as in this case. In all other respects no difference from a mild iridocyclitis was noted.

NOTES, CASES, INSTRUMENTS

DENTAL ACRYLIC IMPLANT FOR USE IN EVISCERATION OR ENUCLEATION OF THE EYEBALL

SQUADRON LEADER M. W. NUGENT*
Winnipeg, Manitoba, Canada

Dental acrylic is an easily obtainable and inexpensive eye implant that can be used after eviscerations or enucleations of the eyeball where an implant is desirable.

In recent years it has become increasingly difficult to obtain satisfactory implants, with the result that many eye sockets are not receiving the cosmetic benefit which an implant affords.

METHOD

In making spherical eye implants from dental acrylic (methylmethacrylate res-

Figs. 1-3 (Nugent). Sizes of implants and embedding in denture flask.

in), the implants are first formed from dental base plate wax in the desired range of sizes as shown in figure 1. An adequate size range includes those varying in diameter from 8 to 20 mm., in 2-mm. differences; namely 8, 10, 12, 14, 16, 18, and 20. These are then invested in the bottom half of a denture flask (fig.

2), by the use of dental stone, only two fifths of each implant being embedded. When the dental stone has set, the exposed wax surfaces are covered with tinfoil one one thousandth of an inch in thickness. All wrinkles must be carefully ironed out. This foil is shown in figure 11, and is

Figs. 4-12 (Nugent). Equipment for making implant.

identical with that used in processing acrylic dentures. The exposed stone surface is now painted with a separating medium, and the top half of the denture flask filled with dental stone. Formation of air bubbles is avoided by carefully vibrating the flask. When this has set, the denture flask is placed in boiling water for 10 minutes. The flask is then opened, and the wax boiled out, after which the flask is allowed to cool and the acrylic is packed.

To prepare the acrylic, 9 c.c. of monomer (liquid), as shown in figure 6, is poured into a mixing jar such as that seen in figure 7. A powder measure is used to add four portions of polymer (powder, fig. 5) to the monomer. If a powder measure is not available add polymer (powder) slightly in excess of the amount required to absorb the 9 c.c. of monomer (liquid). The mixing jar is covered and allowed to stand for five minutes, after which the contents are thoroughly mixed

* Consultant Ophthalmologist, No. 2 R.M.B.,
Deer Lodge Military Hospital.

with a stainless steel spatula (fig. 12) until the color is incorporated. The cover is again placed on the mixing jar, and it is allowed to stand until the mixture can be removed as a "putty-like" mass. This will require about 20 minutes, depending on the temperature of the room and the mixture. This mixture (dental acrylic) is sufficient to make a set of seven eye implants ranging in diameter from 8 to 20 mm., in 2-mm. differences.

The acrylic is now packed firmly into the top half of the denture flask, which represents three fifths of each implant. The acrylic is piled up sufficiently so that it will fill the bottom half of the denture flask, which represents two fifths of each implant. A sheet of wet cellophane (fig. 10) is placed over the acrylic and the two halves of the denture flask are brought together. Slow and even pressure is then applied to the packed denture flask by means of a pressure clamp or dental press. This allows any excess acrylic to escape. When the flask is completely closed it is removed from the press and opened. The cellophane is stripped off and the surplus acrylic cut away. Fresh acrylic is now added to each implant, the wet cellophane again placed in position, and the pressing procedure repeated. This is necessary in order to expel any air bubbles that may have been trapped in the acrylic and not entirely expelled by the first press. The flask is again removed from the press and opened, the cellophane stripped off, and the surplus acrylic cut away. The next step is to line the implant impressions in the bottom half of the flask with tinfoil, close it, and return it to the press. It is now ready for curing.

The method herein outlined can be used in making implants from clear or pink acrylic. A simpler method exists if implants of pink acrylic only are desired. In this instance solutions of waterglass may

be used in place of the tinfoil and cellophane. When the wax is boiled out and while the case is still hot, both halves of the implant impressions are coated liberally with waterglass solution number one (fig. 4), which consists of one part waterglass to six parts of water. This is allowed to stand for two to three minutes, then the excess is wiped away and waterglass solution number two (fig. 4), which is made up of two parts of waterglass to one part of water is applied. When the flask is cold and ready to pack with pink acrylic, the waterglass will be dry and glazed.

It is a matter of individual choice whether clear or pink acrylic implants are used, as one has no advantage over the other. However, because of the simpler and quicker method that can be employed in making implants of pink acrylic, this has become the writer's choice.

The final two steps are those of curing and finishing. The curing of the acrylic must be done by the slow method. To do this the flask is completely covered in water of room temperature, placed over a slow heat, and one hour allowed to bring it to 162°F. It is then held at that temperature for four hours, following which the flask is removed from the bath and bench cooled for approximately one hour. The implants are then dug out and finished off. The finishing is done by first removing the ring of surplus acrylic with a fine emery band on an arbor chuck and then polishing with a soft cotton buff and fine pumice, followed by a clean buff and whiting.

DISCUSSION

Almost all eviscerations or enucleations of the eyeball should be followed by some form of implant within the sclera or Tenon's capsule, as the case may be. The only real contraindication to such a procedure is the presence of infection, mak-

ing adequate open drainage a surgical necessity.

Because of the difficulty in obtaining satisfactory implants many eyes are being removed and no implant used. This is a decided disadvantage to a good cosmetic result, for it permits more sinking-in of the periorbital and peribulbar tissues. Another factor in favor of the use of an implant is that it gives a better bed on which the artificial eye can rotate and to a greater extent helps lessen the starness of an artificial eye that rotates too little or not at all.

Bone, cartilage, or fat implants can be discarded as inadequate. Gold, platinum, tantalum, or vitalium implants, although excellent, are both expensive and, for the past few years, almost impossible to obtain. Mules's spheres are hollow, occasionally break *in situ*, and are also difficult to obtain. The solid glass ball is not to be recommended because of its weight, which increases the possibility of postoperative extrusion. Implants made of dental acrylic (methylmethacrylate resin) have no apparent disadvantages in that they are inexpensive, easily obtainable, light in weight, and well tolerated by the soft tissues of the orbit. To date the writer has had no extrusions or allergies with this type of implant.

In conjunction with the use of dental acrylic implants, accepted surgical methods were used. In enucleations, Tenon's capsule and the extraocular muscles were overlapped in front of the implant, 00-chromic catgut being used, and the conjunctival layer closed separately with 00-plain catgut. In eviscerations, the scleral tissue was overlapped in front of the implant, again with the use of 00-chromic catgut, and Tenon's capsule and conjunctiva were closed separately with 00-plain catgut. Following these clo-

sures 5-percent sodium sulfathiazole ointment was applied, and a pressure bandage placed in all cases. The pressure bandage was not disturbed for seven days, but reinforced when indicated.

All implants of dental acrylic used were spherical in shape. Bizarre shapes were not considered, since it has been shown that the spherical shape is adequate.

The size of the dental acrylic sphere to be used in each case is important. The largest spherical implant that Tenon's capsule, or the sclera, will hold without tension and allowing for adequate overlapping of tissues should be used in all cases. For this purpose sizes ranging in diameter from 8 to 20 mm., in 2-mm. differences, should be kept at hand.

SUMMARY AND CONCLUSIONS

1. The method of making eye implants from dental acrylic has been outlined. This is only a variation in the everyday work of a dental technician and is not necessarily original.

2. They can be obtained easily and inexpensively from any dental laboratory.

3. They replace adequately all other types of implants.

4. To date, no contraindications of their use have arisen.

5. The size of dental acrylic implant to be used is important, and the use of a pressure bandage is to be stressed.

Acknowledgment. The author wishes to thank Warrant Officer W. J. Mitchell of the Canadian Dental Corps, for carrying out the details of technique in the making of these implants, and for keeping our supply adequate during the past two years.

CONGENITAL MEMBRANOUS CATARACT

EUGENE M. BLAKE, M.D.

New Haven, Connecticut

At the March 27, 1944 meeting of the Los Angeles Society of Ophthalmology and Otolaryngology (reported in the *American Journal of Ophthalmology*, 1945, volume 28, number 8), Dr. Etta C. Jeancon related the case of a two-year-old child with congenital cataracts which she thought to be unique. The child was apparently normal in all respects except for the lenticular opacities.

When a discission operation was performed it was found that only an empty capsule existed, and no cortical matter was present. Following the operation, there was practically no postoperative reaction, the pupil was clear, and the fundus seemed to be normal. The parents were of the opinion that the cataract was not so densely white at the age of one year as it had been at birth, and Dr. Jeancon assumed that this was a congenital morgagnian cataract in which complete absorption had occurred. She quoted Dr. Ida Mann to the effect that this type of cataract is caused by lack of development of central fibers, or an early secondary degeneration of these fibers which have disintegrated and softened, the nucleus sinking to the bottom of the capsule. No record could be found of such complete absorption of the degenerated cortex.

This account prompts the reporting of a strikingly similar case seen by the writer in which he performed the operation. On January 28, 1944, the mother, who was a young army nurse, brought her two-months-old baby for advice, having been told at an army base hospital that her son had congenital cataracts. The infant was tiny but well nourished. The eyeballs were noticeably small, the corneas meas-

uring 8 mm. There were an alternating esotropia and a roving nystagmus as well as lenticular opacification. Upon inquiry the mother stated that she had had German measles during the second month of this, her first, pregnancy. When the pupils were dilated by hyoscine the lenses showed a white, asbestoslike opacity, with no clear cortex. Bilateral discission was proposed, and on July 10, 1944, the operations were performed.

When the knife-needle was drawn across the capsule it divided readily, leaving a clear black pupil at once. The same condition was noted in both eyes. No soft lens matter was present, and there was practically no reaction following the discissions. No satisfactory view of the fundi was obtained because of the nystagmus and the small pupils.

In addition to the ocular changes mentioned, the baby had a patent ductus arteriosus.

When seen last, in September, 1945, the pupils were clear and a good fundus reflex was present. There was marked esotropia, apparently alternating, and the child, now 21 months of age, walked about, avoiding obstacles, reaching for lights, and showing other signs of visual capacity. Lenses of +8.00D. were prescribed.

The writer has been unable to find a description of a similar congenital membranous cataract, except the one reported by Dr. Jeancon. Dr. Ida Mann places the time at which congenital morgagnian cataracts are formed as in the sixth month of gestation. Since the mother of the baby here described developed German measles during the second month of her pregnancy it would not seem likely that the membranes present resulted from absorption of cortex, but rather from a failure of cortical fibers to develop.

February 5, 1945

DR. MILTON L. BERLINER, *presiding*

BOECK'S SARCOID

DR. ERNST WALDSTEIN presented an 18-year-old Negro girl who complained of pain in her chest in October, 1944. Her history up to that time was negative except for dysmenorrhea and a mild parametritis. An X-ray picture at that time revealed an adenopathy in the mediastinum and a tentative diagnosis of Boeck's sarcoid was made. She had no cough, no fever, and was anergic to tuberculin. In December a biopsy specimen of a slightly enlarged axillary node was secured, and the diagnosis of Boeck's sarcoid was established. No osteoporosis cystica of the fingers or toes had been found.

The patient was seen for the first time early in 1945. She had a painful and irritated right eye, with numerous keratic precipitates and vitreous opacities. The cornea and retina were normal. For approximately two weeks a grayish, somewhat vascularized nodule with a smooth surface had been visible in the angle of the anterior chamber at the 6-o'clock position. It appeared to be growing rapidly. There was also a pea-sized subcutaneous round tumor in the upper temporal angle of the right orbit. The patient received X-ray treatment of the chest. Eye therapy was purely symptomatic.

Boeck's sarcoid, a misleading name, is a chronic granulomatosis of moderate malignancy, attacking especially the reticulo-endothelial system and in particular the lymph nodes. Involvement of the eye

seems to occur in about 5 percent of the reported cases. The retina is very rarely, and the cornea never, affected. The diagnosis is established by biopsy specimen from a lymph node. Caseation in the pseudotubercle is never present; no organisms have ever been found. The disease has its exacerbations and remissions, the eye lesion either becoming absorbed spontaneously or proceeding to phthisis bulbi or secondary glaucoma with loss of the eyeball.

It appears that Boeck's saracoid is not so rarely found in the eye as is frequently thought.

PENICILLIN IN THE TREATMENT OF PERFORATING INJURIES OF THE EYE

DR. DANIEL M. ROLETT described the results of the use of penicillin in four cases of perforating ocular injuries.

Case 1. Mrs. D. H., aged 66 years, suffered a spontaneous rupture of a glaucomatous eyeball. Enucleation with gold-ball implant was performed. Secondary infection of the eyeball developed with expulsion of the implant. There were general malaise and fever. One hundred thousand units of penicillin administered intravenously checked the infection quickly and effectively.

Case 2. Mr. A. S., aged 41 years, had a traumatic rupture of the cornea with loss of vitreous and injury to the iris, ciliary body, and lens. Surgical repair of the damaged tissues was performed, but five days later infection set in and advanced rapidly despite vigorous routine treatment in the hospital. Penicillin was administered, and 48 hours subsequently the infection was checked.

Case 3. Mr. L. E., aged 49 years, suf-

ferred a perforating corneal wound with secondary infection manifest on the first day after the injury and accentuated on the following day. Penicillin checked the infection.

Case 4. G. H., aged nine years, sustained a perforating injury of the cornea with subsequent evidence of infection. Penicillin therapy was instituted. Recovery was rapid, with restoration of vision to 20/40.

In all these cases smears and cultures taken from the eyes preoperatively and postoperatively revealed heavy growth of staphylococci and some were contaminated by occasional pneumococci.

It was concluded that enucleation of even severely injured eyes should be delayed until penicillin therapy is given a fair trial.

MELANOMA OF THE SKIN WITH OCULAR AND ORBITAL METASTASES

DR. J. R. LISA described a man, aged 68 years, who had a painful skin tumor removed from the chest wall. Eighteen months later there were local recurrence and axillary lymphatic metastases, which were excised. Soon after, there developed multiple subcutaneous lesions, weakness, weight loss, and increasing loss of vision. The patient died within six months, and at autopsy there were found extensive metastases, including those to the eye and orbit.

Discussion. Dr. Isadore Givner reviewed the literature to date and could find only 15 cases verified histologically both as to primary and metastatic foci. Of these, only two, those of Terplan, and of Meigs and de Schweinitz, had the orbit as a metastatic area. In 73 autopsies of patients dying of melanoma, Kreibitz reported 26 as originating from sarcoma of the choroid. Metastatic lesions in the eye are characteristically multiple, flat, and bilateral. Evidence of their being

metastatic is further added to by (1) limitation to certain areas; (2) being surrounded by comparatively healthy tissue; and (3) the presence of blood vessels within them containing cells of the same character.

Of the 15 cases of metastatic sarcoma of the eye, 5 cases were bilateral. The site of origin was 6 times from the skin, 3 times from the mediastinum, and once each from the lid and conjunctiva, stomach, liver, small intestines, eye, and ovary. The sites to which they metastasized were 6 times to the choroid, 6 times to the optic nerve, 5 times to the ciliary body, twice to the iris, and twice to the orbit.

Although the preponderance of evidence is in favor of considering any sarcoma of the choroid as primary, one should bear in mind the possibility that it may be a metastatic lesion and search not only for a primary focus but also for multiple evidences of metastases.

Dr. Olga Sitchevska called attention to a report from the Holt Radium Institute, appearing in the *Lancet*, in which 100 cases were reviewed. Thirty-four patients had metastatic sarcoma because of removal of "birthmarks." She warned that pigmented moles which showed no active growth should never be removed for cosmetic purposes for fear of starting metastases.

RECURRENT DETACHMENT OF THE CHOROID FOLLOWING TREPHINING OPERATION

DR. JAMES W. SMITH recalled that the frequency of choroidal detachment after cataract extraction is well recognized. Bothman and Blaess reported 20 detachments in 143 eyes operated on for glaucoma. Duke-Elder considers detachment of the choroid more common after glaucoma surgery than after cataract operation. The detachment usually disappears after several days and rarely persists for

more than a month.

In the case reported six days following a trephining operation, a choroidal detachment was observed inferiorly. Reattachment took place two days later. The same phenomenon occurred in six days with restoration again in two days. Symptoms ushering in attacks were tearing, visual veiling, and distortion. The third detachment lasted only 12 hours, whereas the fourth cleared in 48 hours. The fifth and last attack occurred three months after operation, and preoperative vision of 20/50 was recovered.

For three months thereafter a convex arc of pigment granules, extending almost to the optic-nerve level, demarcated the area of detachment. Treatment was limited to continual atropine and pare-drine mydriasis.

Discussion. Dr. Ernst Waldstein stated his impression that the type of section used in a cataract extraction is greatly responsible for detachment of the choroid. His first teacher, Czermak, used a subconjunctival cataract extraction the chief features of which were a large subconjunctival pocket and completion of the section by means of special scissors. When, usually after a week's interval, the eyes that had been operated on were examined in the dark room, a large percentage were found to have a detachment of the choroid. In cases wherein the classical method with the Graefe knife was used, this percentage was considerably smaller.

Dr. Dewey Katz urged that Dr. Smith's warning regarding this condition be taken seriously, for these cases of post-operative choroidal detachment are not so benign as one may be led to believe. He recalled a case of bilateral-trephining surgery in which the choroidal detachments with their resulting absent anterior chambers persisted for several months. Dr. Katz placed himself in the group of

operators who secure an incidence of 50 percent of choroidal detachments following sclerectomy. He said he believed that the type of incision influences the frequency of choroidal detachment. His experience has been that it occurs more frequently following the various types of sclerectomy than keratome or cataract-knife incisions. He has recently gained the impression that, in the absence of other contraindications, getting these patients with choroidal detachment out of bed helps to clear up the condition. He had several cases in which the detachments disappeared and the anterior chambers were re-formed soon after the patients were allowed out of bed.

Dr. Smith did not agree with Dr. Waldstein that the type of section employed for cataract extraction will decrease the incidence of choroidal separation. O'Brien observed transient choroidal separation in 93 percent of his cataract operations performed by modern and approved methods. The statement that choroidal detachments are unimportant and that all get well without complications unfortunately appears in several textbooks. Careful review of the literature reveals that many eyes are lost following trephining operations complicated by prolonged choroidal detachment. He agreed with Dr. Katz in emphasizing that the trephine opening, by preventing early re-formation of the anterior chamber, prolongs the choroidal separation. Duke-Elder credits Bothman with the procedure of turning down a strip of superior rectus tendon subconjunctivally over the trephine opening in these cases; but he believed Magitot originated this type of repair.

THYROTROPIC EXOPHTHALMOS

DR. ISADORE GIVNER presented the case of M. J., a woman, aged 34 years, who was seen on April 21, 1944. Her past

history was not significant except for a thyroidectomy performed in March, 1943. Two days following the operation the eyes became more prominent. When seen for the first time her measurements at 105 mm. baseline were 32 mm. in each eye. Vision was R.E. 20/30, L.E. 20/100. Edema of the lids was 3+ and chemosis of the right eye was 1+. The fundi showed only retinal venous congestion. An X-ray picture of the skull showed that the sella turcica was normal in size and shape. The patient was advised to take 3 grains of thyroid daily. The basal metabolic rate was 1+.

On July 21st the patient complained of diplopia, and paresis of the right inferior rectus muscle was present. The visual fields showed a central scotoma for red in both eyes and loss of the supero-temporal field for red in the left eye.

Two X-ray treatments of 40 r each were given to the pituitary region at a one-week interval. Following this the patient's condition became worse, and the exophthalmos measured 33 mm. each eye. Visual fields now showed a temporal contraction for 3/330 white target and a central scotoma for both color and form in each eye.

On August 21st paresis of the depressors of the left eye produced a left hypertropia. The vision was R.E. 20/200, L.E. 3/200.

A Naffziger operation was performed on August 28th. The surgeon reported "little orbital fat and very great hypertrophy of the ocular muscles, which were thick and gray in appearance."

When seen at the last examination exophthalmometric measurements were 18 mm. in each eye (total reduction of 15 mm.). Vision was R.E. 20/20, visual field normal. Vision of the left eye was reduced to perception of hand movements; visual field more contracted, and optic atrophy was present. X-ray pictures of

the optic foramina disclosed that the roof of the right optic foramen had been removed while the left was still intact. This may have accounted for the continued loss of vision due to immediate increased postoperative swelling.

Discussion. Dr. Daniel Kravitz stated that in 1941 Dr. Walter Moehle and he reported two cases of exophthalmos in which the eyes were lost. At that time they divided exophthalmos into two varieties, one calling for early thyroidectomy and the other for other therapy. A great debt is owed to Dr. J. H. Mulvany for so clearly differentiating the two types. Many patients are still being operated upon whose cases have not been adequately classified, with the result that there is progression of the exophthalmos to blindness. Cases like that reported by Dr. Givner should be repeatedly presented before medical societies until the profession is well informed, and cases of exophthalmos are properly classified before operation. This will prevent many cases of post-thyroidectomy blindness.

MACULAR DEGENERATION—A CLINICAL AND PATHOLOGIC STUDY

DR. SAMUEL GARTNER described a brother and his sister who noticed the onset of poor vision nine years ago. At the ages of 47 and 45 years, respectively, they had extensive degeneration of the macula and small foci of degeneration elsewhere in the retina of both eyes. A brother, who died of influenza at the age of 31 years, had poor vision for the last few years of his life. Their parents were cousins of distant degree.

The fundi presented a very similar picture in the four eyes of these two patients. The discs were of good color and the retinal vessels appeared normal. In the macular region there was an extensive area with a gray background and a glazed surface which contained a large

number of irregular, almost black, pigment deposits. A number of smaller pigment deposits, some with a small atrophic zone about them, were found near the disc. The periphery appeared normal. In the case of the woman there were, in addition, a few blood vessels near the disc which had a collar of pigment about them.

The hereditary macular degenerations have been classified according to the age of onset, which is somewhat arbitrary, in as much as there is considerable overlapping. The pathology requires further study, for there appear to be considerable differences in the various groups.

Discussion. Dr. Arthur Linksz said that the conspicuous and very typical sheen of the whole retina in both of these patients suggested to him a heredo-degeneration of the retina rather than macular degeneration. Certainly they did not belong in the groups of macular degeneration of which Dr. Gartner presented such beautiful pathologic slides. Though the discs were of rather normal color and the retinal vessels well filled, there were enough pigment spots scattered over an intermediary area of the fundi to justify the diagnosis of atypical pigmentary degeneration. He agreed that in addition to the sheen and pigment spots there was present a special involvement of the posterior poles. This he believed can be best described as an atrophy of the posterior layers of the retina or of the choriocapillaris or both. The retinal vessels passed the sharp boundary of these lesions unhampered and the deeper choroidal layers appeared intact. However, this sharply outlined disciform lesion, while involving the macular region, was much more extensive than the macula. The male patient mentioned poorer vision in dim light, which is probably further evidence that these cases belong in the large group of so-called tapeto-retinal degenerations.

Dr. Sigmund Agatston agreed with Dr. Linksz in his impression as to the nature of the cases. He would not classify them in the same category with Tay-Sachs disease or juvenile macular degeneration but would consider them atypical central pigmentary degeneration, with normal periphery, without contracted arteries and without any lens opacity. A similar glazed pigmentary degenerative change had been observed following exposure to strong sunlight.

Dr. Gartner said the cases he demonstrated were not exactly like some of the textbook pictures. It is not especially enlightening to quibble about the terminology as the classification is based mainly upon the location of the lesions and the age of onset. The knowledge of hereditary macular degeneration is necessarily limited, since so few of these eyes have been studied histologically. The question as to whether these may be cases of atypical retinitis pigmentosa with macular involvement presents a theory with little to support it. The lesions were predominantly at the macula. The discs and the blood vessels were normal; the lenses were clear, and the peripheral visual fields were normal. It cannot be doubted that these are hereditary degenerations. The parents of the patients were distant cousins and all four eyes of this brother and sister presented a similar picture of macular degeneration.

MULTIPLE NODULAR TUBERCULOUS SCLERITIS

DR. BERNARD KRONENBERG described such a case, which has been published in this Journal (January, 1946).

Discussion. Dr. Olga Sitchevska said she reported a case of primary tuberculosis of the conjunctiva two years ago. An 18-month-old child had a lesion in the conjunctiva of the upper lid with swelling of the preauricular gland. No other tuber-

culous lesion was present in the body. Dr. Sitchevska asked whether many cases of primary tuberculosis of the sclera have been reported.

Dr. Kronenberg, in closing, stated that several cases of primary tuberculosis of the sclera have been reported, but no one has reported nodular scleritis.

LID EDEMA IN DERMATOMYOSITIS

DR. FRANK GRAUPNER presented a case of marked lid edema, of violaceous color, of nine months' duration, in a 40-year-old woman who suffered from dermatomyositis. This rare disease has hitherto been regarded as a nonpurulent polymyositis with degeneration of muscle tissue. Lately, in this country, relationship to lupus erythematosus and similar diseases has been found which would classify dermatomyositis under the vascular disorders. The findings of retinitis with exudates and hemorrhages, as in this case, would substantiate this opinion. Lid edema is one of the first signs of dermatomyositis.

MASSIVE COLLOID DEGENERATION OF THE RETINA

DR. FRANK GRAUPNER presented a nurse with unusually extreme and extensive colloid degeneration of both retinas. The vision was 20/20 in each eye.

Discussion. Dr. Ernst Waldstein said that four years ago he saw a woman, aged 48 years, who had numerous drusen in each eye, and the vision was 20/25 in the right eye. When the patient was last seen, after four years of observation, the drusen had become much more extensive and, while the vision L.E. was 20/20, that of the R.E. was only 20/70. Besides the drusen, there were insignificant pigmentary changes below the macula of the right eye. This frequently seen clinical picture, usually regarded as a harmless

affection, may, therefore, occasionally cause a serious impairment of function, apparently due to pressure of the massive hyaline concretions upon the rods and cones.

Dr. Sigmund Agatston stated that he had seen several similar cases. Some of the patients retain good vision, whereas others do not. Evidently the macula remains unaffected in some cases, just as in paramacular choroiditis.

Dr. Benjamin Esterman questioned the belief that visual impairment occurs if these lesions strike the macula, whereas it does not occur if the lesions fail to involve the macula directly. If this were true, there should be paracentral scotomas in those cases with good central vision.

SCIENTIFIC PROGRAM

PENETRATING INJURIES OF THE EYE: A STATISTICAL SURVEY

DR. WILLIAM F. MONCREIFF and DR. KARL J. SCHERIBEL presented a paper on this subject which has been published in this Journal (1945, v. 28, p. 1212).

Discussion. Dr. Thomas D. Allen said that he would like to know Dr. Moncreiff's indications for evisceration versus enucleation. Recently, immediate enucleation was advised on a patient seen in consultation. Evisceration was done instead, with resultant prolonged healing. It would seem that if there is no infection, enucleation is preferable because healing is more prompt. Evisceration seems to be followed by more inflammatory reaction.

Dr. Vernon M. Leech stated that he is heartily in favor of removal of an injured eye before six weeks have elapsed, if the injury is in the corneoscleral region. He said he recently had an unpleasant experience with an eight-year-old girl who suffered a 6-mm. penetrating wound in the cornea and sclera (3 mm. in each). The parents did not want to have the eye enucleated immediately, although he urged it, so conservative treatment was carried out. The wound was sutured and a conjunctival flap was drawn over it. The eye improved nicely for four weeks and both eyes were watched carefully with the slitlamp every second day. At the fifth week it looked still better, was less sensitive to light, and had good projection, so he told the parents that once a week would be sufficient for observation. The child returned to him in 10 days and at this examination, to his horror, he found in the uninjured or so-called "sympathizing" eye, a sprinkling of cells in the anterior chamber and half a dozen agglutinations on the posterior surface of the cornea. This was six and a half weeks after injury. The offending eye was removed within three hours; a week later no cells were seen in the anterior chamber of the other eye, and the agglutinations had become absorbed. The eye was saved, and visual acuity remained unimpaired. To say the least, this was "too close for comfort."

Dr. Gail F. Soper stated that it was surprising to note how many in this series were cut by spectacle glass. He had been under the impression that this was not a frequent cause of injury. He said he saw a patient a few years ago whose eyeball had been cut by glass from the rear-view mirror.

Dr. G. H. Mundt said he noted that in about 50 percent of the cases sulfona-

mides were used. He asked what Dr. Moncreiff was doing with penicillin in perforating injuries, and how they progressed in comparison with the use of other chemotherapy.

Dr. William F. Moncreiff, in closing, said the question of the relative merits of evisceration and enucleation had not been discussed in his paper, and he had nothing new to offer on this point. Aside from the obvious necessity of evisceration for panophthalmitis or severe endophthalmitis, which no one disputes, there are the extremely mutilating penetrating or crushing injuries of the eyeball in which enucleation would be technically very difficult, and evisceration is therefore more satisfactory. Of course, it is theoretically possible that uveal tissue remaining in the emissaria in these eyes may give rise to sympathetic ophthalmia, but few operators seem to regard this as an important risk.

Penicillin was not used in any case during the period of time covered by the report; during that time penicillin was not generally available for civilian use.

He emphasized that some of the data suggested that in many cases of penetrating injury, a few hours' delay in operating may be less important in the final outcome than the considered decision of a consultant of mature judgment, as to whether the nature and gravity of the injury call for primary enucleation or permit conservative surgery with a reasonable prospect of success.

CHRONIC POSTTRAUMATIC SYNDROMES LEADING TO ENUCLEATION

DR. BERTHA A. KLIEN presented a paper on this subject which has been published in this Journal (1945, v. 28, p. 1193).

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.
Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Manuscripts should be *original copies*, typed in *double space*, with wide margins.
Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 E. Wisconsin Ave., Milwaukee 2, Wisconsin.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

EDUCATIONAL AIDS

In the Irving S. Cutter Memorial number of the Quarterly Bulletin of Northwestern University Medical School (1946, volume 20, number 1, page 71), there appears an article by Tom Jones, B.F.A., professor of medical and dental illustrations, University of Illinois Colleges of Medicine and Dentistry of Chicago. It is an entertaining and thought-provoking study of the use of words, pictures, slides, charts, diagrams, models, specimens, and motion pictures as teaching media in medi-

cal education. The author emphasizes the "gain that results from their coördinated teamwork." He points out that the "progress in the development of visual aids to teaching has been so rapid within the last few decades that it has outstripped our ability to understand them or to use them effectively and also to comprehend their full relation to medical education. . . . A very large number of teachers in medical schools are lagging behind in their knowledge and utilization of visual teaching technics." He pleads for what might be

termed the creation of an environmental aura of visual stimuli to foster chains of association which would require both an unconscious and conscious effort. In other words, blank wall spaces in the halls, class and lecture rooms, and in laboratories should be covered with teaching charts, photographs, diagrams, and so on.

Nearly every teacher for centuries has been aware of the value of visual aids in carrying his ideas across the average high threshold of resistance put up by the pupil. The living subject used in clinics, the lantern slides and motion pictures shown in lectures, charts, diagrams, and models displayed in exhibits, and so on, have been universally used with advantage for all purposes, from selling of a commercial article, particularly stimulating in the territories of hosiery and lingerie, to mortuary displays as well as in strictly educational ventures. In fact, visual aids are used to demonstrate the use of visual aids. No matter where we turn in these days, vigorous visual aids as also auditory ones clamor for our attention, more or less stridently, in more or less good taste, and more or less off-color. So there must be something to the idea. Most children know more about the comic-strip characters Li'l Abner or Blondie, than they do of Abraham Lincoln.

The Army and Navy used visual aids in all their training courses, no matter what the subject, and with great success. It was found that much more could be taught in a shorter time and retained longer through motion pictures, especially sound-recorded, and particularly if there was a bit of humor added somewhere.

This is not to belittle the use of visual aids. Far from it. The medical teacher should become acquainted with all media and learn to integrate them to the best advantage.

It is important here to note the plans

recently set afoot by the American College of Surgeons to sponsor and support a program to develop teaching films on all surgical subjects, including ophthalmology. The plan is a 10-year one, it is expensive and painstaking, but if it is successful, as no doubt it will be, the program will have enormous reward.

There is developing a new commercial profession in our midst, that of "visual aider." It may rival that of radio, some day, and undoubtedly will be hitched to television too. The medical educator should not scorn these, often garish, techniques, but should be placed in the way of becoming acquainted with them in order to utilize them in his teaching more effectively than in the past.

An institute of visual aids for the teaching of ophthalmology would be a great boon. Material could be devised, collected, and distributed, and the words and deeds of great ophthalmic surgeons and teachers could be made available to all medical schools almost on the instant demand. The American College of Surgeons is taking a great step forward in this direction. The Academy of Ophthalmology and Otolaryngology and the American Medical Association also play an active role, although probably unconscious of the ultimate goal at the moment.

But is it necessary to await the founding of such an institute? Since this medium was added the motion-picture programs of the conventions of the Academy and the American Medical Association have been their most attractive features. The pictures have been, as a rule, cleverly devised to demonstrate some particular point or other. Perhaps some of these films were amateurish, but one can see a calculated and, at times, a decidedly professional touch forming.

There is also a collection of surgical films made by the Army and Navy during the war. Many of these are splendid. If

the responsible authorities as well as authors of private civilian films would deposit copies, say in the College of Surgeons or, preferably, in the Army Medical Museum, starting right now, an immediate and impressive collection could be made, and methods of distribution on a loan basis could be set up. Not only films and pathologic slides, but also lantern slides, copies of diagrams and charts, and so forth, could be made available to teachers, medical societies, and ophthalmologic clubs, either for the asking or for a small fee.

The quality of the various forms of visual aids is steadily improving, due to new developments, inventions, materials, and techniques. The art of the preparation of a proper and dramatic scenario is sweeping forward in extraordinary waves. Ophthalmologic societies and teachers need to be informed and kept up to date on these things. Why not establish a joint ophthalmologic committee to investigate these advances, publish frequent reports, and help to keep us so informed?

Derrick Vail.

CORRESPONDENCE

REPORT ON II PAN-AMERICAN CONGRESS OF OPHTHALMOLOGY*

Montevideo, Uruguay—November, 1945
Editor,

American Journal of Ophthalmology:

It has been a bit difficult for me to decide what sort of picture to paint for you. Conventions come and go; they have many features in common, yet they have—if they amount to much—one or more unique characteristics. It would be impossible for me to abstract the papers; I have a few abstracts, but they are not very illuminating nor revolutionary. Most

of the papers were given in a foreign language, and I must confess I didn't understand very much of what was said. But the general over-all atmosphere, the good comradeship, the setting, the personalities, the hospitality, the *esprit de corps*, the earnest seriousness of the delegates, both young and old, to give their best—all of these were most noteworthy.

We think in terms of the Academy and the American Medical Association. These organizations have been active for many years. Can you imagine attending the *first* Academy meeting or the *first* interstate ophthalmological meeting? That is just the sort of meeting this convention was, for here at Montevideo, Uruguay, the professors and practicing ophthalmologists of the Latin-American countries met as a group on a common ground for the very first time in history! True, this was the II Pan-American Congress of Ophthalmology, but the I Congress was held in Cleveland, in 1940, and only about 20 Latin Americans were present. In Montevideo there were over 140. The first Congress was very far from their home; to the Latin Americans from, say, Uruguay, Chile, or Argentina, the trip to the United States was as formidable as a trip for us from here to South Africa, for the transportation was decidedly more difficult then than it is now, and their finances, in general, are not, and have not been, so good as ours.

The amazing discovery I made was that until recently it has been much easier to go from Buenos Aires to Lisbon, Paris, Rome, and London than to any part of the United States, and almost as easy to go from Santiago and Lima to Europe as to the United States. Furthermore, the Andes form an almost impassable barrier from the West Coast to the East Coast; consequently, the crossing was a most rare occasion, and had never been undertaken by any large number of ophthalmologists.

* Read before the Chicago Ophthalmological Society.

This was, therefore, the very first time East met West in South America, and seldom before did any single ophthalmologist go from Central America to South America; or vice versa. Why should they? What could "the foreigners" give them? Why shouldn't such time be spent in well-known centers of learning in Europe?

A word now about the formation of the Pan-American Congress. It was an outgrowth of the International Congress in Cairo, 1936. There Harry Gradle met Moacyr Alvaro, and they, with a few others concurring, proposed an attempt at uniting the ophthalmologists of the Americas. They realized Europe was ripe for self-destruction and that the Americas must depend upon each other for the preservation and advancement of the knowledge and science of ophthalmology.

You know with what success the I Pan-American Congress was held—yet it was attended by very few from Central America and South America. The papers were briefed and *read* as briefed, the translation being thrown on the screen for the benefit of those who had language difficulties.

One disadvantage of this method was that the audience could not take home with them more than a memory, and that often inexact, of what was said.

This time the officers decided to have the papers abstracted and the abstracts *printed*, so that we could read what the author said, both before and after the presentation. We wished they had attended our Academy meetings and copied our Academy procedure; namely, the use of the blackboard to announce the speaker and his topic. Personally, I think a combination of the two methods would work out better, for I found it extraordinarily difficult to sit through several hours of a session in which I often didn't know even which paper was being presented. This is

not a true measure of my intelligence, because (1) the program was not followed exactly, (2) practically all announcements were made only in Spanish, with little consideration for the few of us from the United States.

However, we could not miss the impact of personalities, their earnestness, their enthusiasm, their camaraderie. Two of the Kellogg-fellowship graduates of the Illinois Eye and Ear Infirmary were there—Daniel Silva of Mexico City and Manuel da Silva of São Paulo—also, several who had trained elsewhere in the United States. There were older men there, too; forceful leaders in their respective communities. I should like to mention and characterize all of them, but that would be impossible. Some of those who particularly impressed me I had met before, in or from Mexico City, Guatemala, Lima, Santiago, Buenos Aires, Montevideo, São Paulo, Rio de Janeiro, and Havana. We all know and love Moacyr Alvaro, who has visited Chicago on numerous occasions.

Dr. Alvaro speaks our brand of English, except when he is with an Englishman, French when he is with Frenchmen, Spanish when he is with those who speak Spanish, and Portuguese when he is at home. And I've been told that he is almost as fluent with German and Italian. He has a marvelous memory, a clear mind, and a facile tongue.

Some of you will remember Dr. A. Torres Estrada of Mexico City, who has attended one or two Academy meetings. He is a short, well-built man, somewhat retiring, but a most genial personality, who impresses one with the fact that he knows ophthalmology and has a lot of ability, skill, and diplomacy.

Tomas Yanes of Havana, Cuba, headed the Cuban delegation. He, also, is a frequent visitor to the States, and is a member of the Academy. He is a human

dynamo. His Spanish is so soft and fluid, it flows off his tongue. His hands and heart are in every word. He is dynamic, but he is so very careful not to hurt the feelings of anyone. He was accompanied by Dr. Branly, and together they saw to it that Cuba was chosen for the next meeting.

A. Vázquez Barrière of Montevideo was the president of the executive committee. He is large, genial, punctilious, efficient, quiet, with an old-world dignity that cannot be ruffled. He had two right-hand men: one his son, tall and stately, the counterpart of his father; the other, the secretary general, R. Rodriguez Barrios, a most affable man, who was never in a hurry, but was always everywhere, oiling the machinery, aiding here, directing there, and crazy to learn. He spent a great deal of time with us North Americans and thanked us profusely for talking to him in English. One should watch him for important advances in ophthalmology.

R. Pacheco Luna had left Guatemala City the day before we arrived there, but we thoroughly enjoyed him in Montevideo. He is one of the strong men in ophthalmology and intensely interested in the integration and strengthening of the bonds between all the Americas.

There were so many great men there about whom I should like to tell you, but time does not permit. However, I must mention J. Valdeavellano, a man of small stature, whom you must know to appreciate; but the more you know him the greater is your respect and admiration. He is the Professor of Ophthalmology in the oldest university in the Western Hemisphere, at Lima, Peru. His spoken English is not very good as yet, but he speaks French and German with ease. He is a young man, with great ability. Let me say here that if we would only learn Spanish and read some of their periodicals and books we would find that

they are by no means behind us, except in numbers of talented men. This defect they are slowly remedying.

The delegation from the United States consisted of: Mrs. Merrill Brown, National Society for the Prevention of Blindness; Lieut. Comdr. Griffey from the Department of State; Capt. C. A. Swanson, U. S. Navy; Dr. Conrad Berens, Dr. Joseph Pascal, and Dr. Ramon Castroviejo of New York City, Dr. Paul Tisher of New Britain, Conn., and myself.

Most of the Argentinians absented themselves because they felt that coming from a dictatorship country, they could not conscientiously attend a democratic congress. On our way down, we had stopped in Buenos Aires (B. A. for short), for several days, and there became acquainted with several outstanding men, one of whom, Dr. Francisco Belgeri, had a very prominent part in the Congress. He was distraught because the political situation in Argentina was so bad that the doctors had agreed not to leave the country at this time, even to go across the river Plata.

The setting for the Congress was marvelous. Consider, if you will, 140 delegates and about 60 wives, taking over a large hotel at Atlantic City or Coronado Beach; only our beach was six times as wide and very much longer, and there is *no boardwalk!*

The Uruguayan government was so interested in making the Congress a success that they made an extraordinary arrangement with the Hotel Miramar to have it opened for us just before the summer season; they arranged for all delegates to have a special rate—we paid for the rooms, and the government for the food (*but not the drinks*). The evening meal was almost always a banquet. And such food! It was better than first-class passage on a transatlantic liner! In addition, the president of the Republic, Juan Jose

Amezaga, presided at the opening session and honored us with his presence at a lavish cocktail party given by the Uruguayan Ophthalmological Society. The hotel was about seven miles from the center of the town, and buses ran every 30 minutes, and taxis whenever you wanted them. The country is not too flat, but there are no real hills; that is, it's slightly undulating. The weather was not too hot, and it didn't rain too often—usually at night. The water was a little chilly but invigorating, and an early morning walk or sprint along the beach, followed by a dip in the salt water, made a perfect appetite for breakfast and gave zest to the opening of the new day, even after a late banquet.

The meal hours were something! Breakfast in your room whenever you wanted it. Luncheon at any time from 12:30 to 2:45; cocktails at 7 or 8 o'clock; dinner at 9 or later.

The Inaugural Session, held in the Senate chamber was very impressive. The President of the Republic and most of his executive officers were on the dais, and the officers of the Congress, just below on the platform. Midway, and to the left, on another elevated platform, were the ambassadors of all the countries represented by the delegates. We delegates were scattered about in the seats of the senators.

We heard a few words from the Minister of Public Instruction and then, both in Spanish and English, remarks from the President of the Pan-American Congress. I am sure you will want to hear what he said, for it "caught fire."

Dr. Harry Gradle's Presidential Address

"This, the second meeting of the Pan-American Congress of Ophthalmology, marks an important epoch in the history of ophthalmology in the Americas. For two years this has been postponed, not only because of travel conditions imposed

by the war, but even more because of the handicaps upon science that unleashed brutality produces. But now we can gather in quiet and peace to describe and discuss how best we, the ophthalmologists of the Western Hemisphere, may aid our people, and it is solely for that purpose that the Pan-American Congress of Ophthalmology exists.

"But a forum of this character must be more than merely a meeting place for the exchange of scientific ideas. To be of real value to all of its members, there must be constructive aspects that will tend to advance the science of ophthalmology in all parts of the world inhabited by members of the P.A.C.O. The constructive phase of the Society cannot be confined to the time of the meetings alone, but must live with the members day by day, and night by night. It must be a power, a force, whose sole object is the advancement of the science of ophthalmology, and to which the members can turn as necessary. Your Officers of the P.A.C.O. are endeavoring to supply that force by Ophthalmologia Ibero-Americana, by the Kellogg—Pan-American Fellowships in Ophthalmology, and by the work of the various committees whose reports you are to hear within the next few days.

"By practical experience in the United States of America and in Brazil, it has been found that the most potent factor in the elevation of the standards of ophthalmology is the existence of a joint Board for the purpose of setting up such standards and for the voluntary examination of men who wish to be recognized by their fellows as qualified in ophthalmology. To that end, I propose the development of a South American Board of Ophthalmology, dedicated to the elevation of the standards of training and of the practice of ophthalmology. Such a Board should, of course, be an independent institution, originated by the educa-

tors in ophthalmology, and supported by all of the local and national ophthalmological societies. Each country should be represented by elected representatives in the proportion of one for each 100 ophthalmologists in the country. The Board should meet once a year and determine which of the applicants from all the countries are eligible for examination. Then the examination should be determined upon, and, upon his return home, the examination should be given in each country by the elected representative, assisted by as many ophthalmologists as he may deem necessary. Only those candidates approved by the General Board should be eligible for the examination. Upon successful completion of the examination, a certificate should be granted by the Board, and eventually such certificate will be required for appointment to hospital or university positions."

Dr. Conrad Berens then gave a few very appropriate remarks about the pleasure we English-speaking delegates had at being present.

After a short intermission, we reassembled in executive session, where committees were appointed and minor business transacted.

Some papers prepared by delegates who could not get there were read by others; for example, Saul Sugar's paper on "Gonioscopy and gonimetry," Harry Gradle's on "Preglaucoma," Peter Kronfeld's on "New viewpoints on glaucoma derived from gonioscopy," and George Guibor's on "Surgical treatment." One paper was given in French. During one of the later sessions Dr. Arruga arrived from Barcelona; he was at once ushered to the platform, and the meeting was his. He is a most attractive person, a typical Latin gentleman, always at ease, but you can see fire in his eyes.

We have much to learn about entertaining foreigners and about the value of ambassadors and consuls; for example,

the Cuban delegation came, for the most part, as representatives of the Cuban government. Their president is a physician, a friend and patient of Dr. Yanes. They were most anxious to make an impression upon the ophthalmologists of the Americas. They advertised Cuba everywhere and all the time. The newspapers gave them considerable space. They also went down the West Coast and back up the East Coast. Everywhere they went they entertained the local ophthalmologists, with the help of their ambassadors, and were, in turn, entertained. It was a veritable triumphal procession. Dr. and Mrs. Tisher and Mrs. Allen and I were included as soon as we caught up with them at Lima, Peru. It was a party here, a banquet there, tea or cocktails, or a reception, a dedication of a plaque in honor of a local ophthalmologist, or a launch trip around some interesting islands, a trip to a new clinic, or hospital, or simply a shopping trip for ladies.

It is my impression that things went smoother, and we became better acquainted because the women went along. The men swapped professional experiences and the women family topics, the result being a warm "simpatico" relationship, which is so very valuable south of the Rio Grande.

Our travel time was so arranged that we never flew two days in succession, except in one instance, but had one to four days' rest between flights. For example, we had time in Merida, Yucatan, to go out to see the old Mayan temple ruins (pyramids) at Chi-chi-nitza. We met Dr. and Mrs. Tisher in the plane, en route to Guatemala. We had a good time in Guatemala City, not only to visit with Dr. Quevedo, but also to see the religious rites of the Indians up in the mountains at Chi-Chi-Castenango. We visited the Gorgas Hospital and the leprosarium at the Canal Zone, where Dr. Robinson Har-

ley, a student of William Benedict, was our host.

It was in Lima we expected to rest up, but we were on the go every minute, till we nearly dropped. There was a special Ophthalmological Society meeting an hour after our arrival. This was followed by a banquet that lasted till well past midnight. The Cuban ambassador, Dr. Rodriguez, and his wife, a most charming American woman (she, by the way, was the surgical nurse of the Columbia University Eye Department), were there. The next morning we went to several clinics, most modern in every respect, while the ladies shopped; country club for lunch, then the Anglo-American Hospital, then tea and cocktails, then a private banquet at Professor Valdeavellano's home, where we were overpowered by the importance of the other guests, the beauty of the home and garden, and by the repast, which outshone any smörgåsbord anywhere. Early the next morning (I don't know when those South Americans sleep), they called to take us to the oldest university in the Western Hemisphere, and the museum. Then a quick lunch (6 courses—1 hour, 30 minutes). Time out here for one hour of shopping, then tea; then dress for another private dinner.

The next day Dr. J. Raffo, who had studied with Drs. Benedict, Wheeler, and Berens, took us on a motor launch out of the harbor, at Lima, around some very imposing islands. On the far side, basking on projecting rocks, were thousands of sea lions and millions of birds. They told us that when the droppings become 10 to 12 inches deep, it is worthwhile to mine the guano for fertilizer.

After the Congress, we spent four days in São Paulo, where Dr. Alvaro was a most thoughtful host. We were shown the city, both by day and by night; his home, his office, and his clinics were most attractive. Like Rome, São Paulo is situated on many hills. It is a city with character; and

the people are much as we are—ambitious, energetic, and forward-looking.

On the way home from Rio, I went up the Amazon about 1,000 miles to see what is being done by the Institute for Inter-American Affairs to assist the Brazilians in modern sanitation, the prevention of disease, and the keeping of vital statistics. I spent nearly 24 hours on a launch on the broad waters of the Amazon, and then a day in a town, Itacoatiara, about 150 miles downstream from Manaus, where no doctor has ever lived.

We visited with Dr. and Mrs. Perret-Gentil in Caracas, Venezuela, a beautiful town, over 3,000 feet above sea level, where the houses cling to the side of the mountains, the air is invigorating, and the people most industrious. And finally, on our return, via Miami, we had a most friendly visit with Dr. and Mrs. Nelson Miles Black.

(Signed) Thomas D. Allen, Chicago

YOU'VE LOST AN EYE! SO, WHAT?

Editor,

American Journal of Ophthalmology:

"The loss of an eye is not so much of a handicap as might be supposed."

However surprising and apparently paradoxical the statement, coming from a lady of quality who is an authority of experience and standing, it deserves respectful consideration as a contribution to clinical and social ophthalmology. When such information brings with it constructive counsel and a humanitarian appeal of the highest spiritual significance, any hesitation to accept and approve wholeheartedly must seem narrow-minded if not antisocial. What indeed could touch us more deeply than a call for common effort to spare the partially blinded soldier any additional hurt, any lowering of morale, any hindrance to rehabilitation.

It at once arouses our sympathy and enlists our full support. However, there are implications in Lady Duke-Elder's thesis which in all conscience call for further consideration.

Monocular blindness is not a war casualty alone. It is, unfortunately, all too common in industry, in sports, in traffic, even in the home, and in every case presents a continuing hazard of total and irremediable blindness.

The prime desideratum, here, is the prevention, if possible, of any further loss of vision by injury. This calls for intensive warning of individuals and groups, the inculcation of caution, insistence on the use of protective appliances and precautionary measures, a campaign of legitimate propaganda for community eye-safety. To play down the loss of an eye is to discount our moral responsibility, it does marked disservice to this sight-saving project and, indirectly, to every potential victim. There are factors of safety in most ocular hazards. The double representation of the eye is one, perhaps the most important one. Its loss will not be regarded lightly when "there is only one eye between you and total blindness." That loss of the remaining eye due to injury is statistically infrequent offers little consolation to the individual victim. The favorable (?) figures may be explained. "Once bitten, twice shy." The one-eyed operative avoids reemployment in a hazardous trade and

uses every protection and precaution available.

The visual field and safety. The claim that only one fifth of the field is destroyed when an eye is lost, while mathematically tenable is hardly fair when it ignores the complete loss of an invaluable safety factor; that is, vision on one whole side. This field with its highly developed sense of motion is of paramount importance in warning of danger from moving vehicles and flying missiles, approaching from the side (far off center) and even a bit to our rear. It is true that we can turn the one remaining eye and the head whenever we wish to look into the "lost" area, but unless a danger signal makes this adjustment instinctive and instantaneous, it is of no value whatever as a factor of safety. In lower animals the eye is located well to the side of the skull, and the entire monocular apparatus, left and right, is available as a lookout for trouble. In man, the eyes have come to the front, and the temporal field alone, of each eye, becomes the guardian angel of sight and safety. The loss of this protective factor now constitutes an actual hazard.

These considerations should lead us to the all-important work of conservation of vision and the prevention of blindness, while we still hold to the high purpose imposed by Phyllis Duke-Elder's stirring appeal.

The loss of an eye is, indeed, "as much of a handicap as might be supposed."

(Signed) PERCY FRIDENBERG, New York

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. General methods of diagnosis
2. Therapeutics and operations
3. Physiologic optics, refraction, and color vision
4. Ocular movements
5. Conjunctiva
6. Cornea and sclera
7. Uveal tract, sympathetic disease, and aqueous humor
8. Glaucoma and ocular tension
9. Crystalline lens
10. Retina and vitreous
11. Optic nerve and toxic amblyopias
12. Visual tracts and centers
13. Eyeball and orbit
14. Eyelids and lacrimal apparatus
15. Tumors
16. Injuries
17. Systemic diseases and parasites
18. Hygiene, sociology, education, and history
19. Anatomy, embryology, and comparative ophthalmology

1

GENERAL METHODS OF DIAGNOSIS

Agundiz, Teodula, Jr. **Clinical applications of angioscotometry.** *Bol. del Hosp. Oft. de Nuestra Señora de la Luz*, 1945, v. 3, May-Aug., pp. 33-49.

The scope of this article covers technique (which includes a great deal of patience); vascular structure of the retina; and consideration of other anatomic details. (9 figures.)

W. H. Crisp.

Della Casa, F. **An adaptometer for the general practitioner.** *Ophthalmologica*, 1943, v. 106, Sept.-Oct., p. 143 and p. 189.

Increased night traffic makes the testing of dark adaptation desirable. The author describes a simple adaptometer that is sufficiently exact for the general practitioner and not expensive. The instrument consists of a horizontal hollow cylinder which is black on the outside and white on the inside. On the inside of the rear wall is a Landolt ring that can be turned. The front wall has

a horizontal slit through which the patient looks into the cylinder. Light from an enclosed lamp is admitted through openings in the top, and the illumination can be varied between 570 and 0.05 Hefner units. The instrument and its parts were standardized by the Swiss Federal Office for Weights and Measures. Preadaptation is made on the instrument itself. The author discusses the literature on the subject of adaptometers and compares his instrument with existing ones. He also observes that dark adaptation is delayed in one-eyed people and the aged. (Bibliography.) Max Hirschfelder.

Evans, J. N. **A visual test for infants.** *Amer. Jour. Ophth.*, 1946, v. 29, Jan., pp. 73-75.

Friedman, Benjamin. **Measurement of relative exophthalmos by roentgenography.** *U. S. Naval Med. Bull.*, 1945, v. 45, Sept., p. 482.

The details of a method for measurement of relative monocular exophthalmos by the X ray are described. Contact

lenses with central lead dots are used. The position of the patient's head is precisely controlled while the Xrays penetrate at an angle of 35 degrees. The relative positions of the projected shadows of the dots indicate the presence and degree of monocular exophthalmos. Changes in a progressive exophthalmos can thus be measured and recorded. The method is of no assistance in measuring bilateral exophthalmos.

Morris Kaplan.

Losada, J. Colloidometry of the anterior chamber. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Jan., pp. 43-45.

The determination of the albumin content of the aqueous is of diagnostic and prognostic importance. The concentration of albumin is measured by the colloidometer of Rønne combined with the slitlamp. The colloidometer consists of a Recoss disc which carries a series of gray glasses of different transparency graduated from 0.25 to 3.50 photopters. The upper one fifth of the slitlamp beam is left unobstructed by the glasses. The tone of the unobstructed light passing through the cornea is the standard. By selecting the proper glass the tone of the light passing through the aqueous is made to match that of the light passing through the cornea. Each glass has a value in photopters which indicates the concentration of albumin in the aqueous.

J. Wesley McKinney.

Wagenaar, J. W. A simple method for viewing the fundus stereoscopically without a stereoscopic instrument. Ophthalmologica, 1943, v. 105, Jan., pp. 13-23.

The author demonstrates that one can see the fundus binocularly and stereoscopically by means of indirect

ophthalmoscopy and a 20-diopter lens. The ophthalmoscopic mirror must be held between the eyes of the observer, and the observer must turn his head slightly in order to bring his optic axes nearer together. The geometric optics of this arrangement is discussed. The author also describes a new method for binocular observation of the fundus by means of two interlocked electric ophthalmoscopes.

Max Hirschfelder.

2

THERAPEUTICS AND OPERATIONS

Ahmed, N. Sulfonamide amblyopia and its treatment with nicotinic acid. Indian Med. Gaz., 1945, v. 80, March, p. 146.

Two cases of optic atrophy following the administration of sulfonamides are described. Both patients received large doses of nicotinic acid by mouth and intramuscularly. The patient who received this treatment promptly after the onset of the disease made a rather satisfactory recovery whereas the other was not benefited after a delay of five months. The author suggests that the sulfonamides inhibited the synthesis of vitamin B in the intestines.

Morris Kaplan.

Bentley, Neil. Penicillin in ophthalmology. Jour. Mich. State Med. Soc., 1945, v. 44, July, p. 706.

In selected diseases the effects of penicillin are amazing. In cases of orbital cellulitis, thrombophlebitis, and meningitis it surpasses expectations; in uveitis it does not seem to be of much value. In conjunctivitis of a stubborn nature it is worthy of trial.

In the limited experience of the author, local use is often followed by dermatitis of the eyelids. However, it has been successfully used by many for

blepharitis and conjunctivitis. As yet no ointment has been developed that retains its potency.

Theodore M. Shapira.

Blok, C. J. Eye ointments and their therapeutic effect. *Ophthalmologica*, 1943, v. 106, Aug., pp. 57-65.

Blok criticizes the usual emulsion of the "water in oil" type as a vehicle for drugs in eye ointments. He experimented with emulsions of the "oil in water" type and prefers vehicles of a mucous consistency, such as 3-percent tragacanth and 2-percent pectin. Drugs, particularly alkaloids, pass into the eye more readily from such a vehicle, and their concentration may therefore be very much less. The author also stresses the advantage of an alkaline reaction of the ointment, which can be brought about by adding boric acid and sodium biborate to the mixture. An ointment which contains 0.2-percent pilocarpine in an alkaline tragacanth base was as effective as the 2-percent concentration in the usual media.

Max Hirschfelder.

Buerki, E., Schmid, A., and Saubermann, G. Experience with cibazol in ophthalmology. *Ophthalmologica*, 1943, v. 106, Sept., pp. 113-135.

The sulfanilamide preparation, cibazol, was given to 340 patients in the eye clinic in Basel. The preparation was used locally in a 10-percent ointment and internally. The treatment was effective in erysipelas, ophthalmia neonatorum, serpiginous ulcer, catarrhal corneal ulcer, phlyctenular keratoconjunctivitis, gonorrheal iritis, and certain intraocular infections. It was less effective in lid abscess, chronic and phlegmonous dacryocystitis, blepharitis, and pneumococcus conjunctivitis. The drug had no value in rheumatic and

tuberculous iritis, nor in conjunctivitis caused by diplobacilli or trauma. No significant ill effects from the medication were observed.

Max Hirschfelder.

Buerki, E. The therapeutic use of Privin (Ciba) in ophthalmology. *Ophthalmologica*, 1942, v. 104, Nov., pp. 254-263.

Prievin (Ciba) is naphthyl-methylimidazolin-hydrochloride. It causes constriction of blood vessels, but, unlike adrenalin and ephedrine, this effect is not followed by hyperemia. In the eye clinic at Basel the drug was effective in acute and chronic conjunctivitis and in posttraumatic and postoperative irritative conditions of the anterior segment. It can be used with zinc sulfate, colloidal silver preparations, and local anesthetics.

Max Hirschfelder.

Dean, M. On the use of atropine in postoperative hyphemas. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, pp. 46-49.

The author reports two cases of severe hyphema which failed to show any evidence of absorption until atropine was discontinued. The hyphema then cleared up rapidly. Atropine may promote intraocular hemorrhage by a combination of peripheral vasodilation and individual sensitivity.

J. Wesley McKinney.

Dejean, C. and Roux, N. Bilateral contracture of accommodation by abuse of sulfonamides. *Bull. Soc. d'Opht. de Paris*, 1939, Oct.-Dec., pp. 582-584.

A temporary myopia due to bilateral spasm of the ciliary muscles developed as a result of intoxication from sulfonamide medication given for a gonorrheal infection. An excess of sulfa

drugs, like eserine, can produce a spasm of accommodation.

Morton R. Cholst.

Erpf, S. F., Dietz, V. H., and Wirtz, M. S. Prothesis of the eye in synthetic resin. Bull. U.S. Army Med. Department, 1945, v. 4, July, p. 76.

The authors feel that an artificial eye can be fitted readily by the dental officer in coöperation with the medical officer. They describe a simple method of fabrication which is based on research conducted by the medical department of the U.S. Army.

The advantages of a plastic prothesis over a breakable glass one are discussed. A plastic prothesis is easier to replace and can be made without expert skill. The substance used is the basic synthetic resin, methyl methacrylate, which is easily obtained and easily handled. The entire method is described clearly and completely.

Francis M. Crage.

Greenberg, M. M. The use of acrylics for enucleation with implant and as a temporary prosthesis. The Military Surgeon, 1945, v. 96, March, pp. 269-271.

Acrylics, which are light, hard, organic plastic substances and produce no reaction when buried in tissues, are ideally suited for implantation into the orbit. The author uses a grooved hollow sphere, 16 mm. in diameter and 2 mm. thick. The sphere weighs less than a glass sphere of equal size, withstands pressure of 150 pounds, withstands rapid changes in temperature, is readily sterilized, and is not apt to be expelled by the tissues. (Bibliography.)

Melchior Lombardo.

Kohout, J. J. Diathermy tip for retinal operations. Bull. U.S. Army Med. Dept., 1945, v. 4, July, p. 10.

Standard electrocoagulating units in many of the Army hospitals do not have electrodes satisfactory for ophthalmic work. Captain A. G. De Voe of the Medical Corps has devised a perfectly satisfactory tip which can be used directly with the electrocoagulating unit in the usual surface and penetrating diathermy for retinal detachments. It is made of 2-mm. capillary glass tubing and the fine steel wire that is supplied as a stylet for 22-gauge, 3-in. hypodermic needles. Platinum and tantalum have no advantages over this steel tip. It is easy and economical to make, and sparking has not been excessive nor detrimental.

Francis M. Crage.

Kohout, J. J. Prosthetic device for support of eyelids. Bull. U. S. Army Med. Department, 1945, v. 4, July, p. 117.

When an eye and the lower lid are lost, the swollen, unsupported upper lid, which is frequently without levator support, becomes increasingly disturbed in function. When a lower lid, dislocated by division of the inner canthal ligament becomes adherent to the maxilla, through scar tissue, the upper lid becomes edematous, and its metabolism is disturbed. The author describes a method for making an acrylic prothesis which is designed to support the upper lid until the tissues have recovered to a stage where plastic surgery is possible. Francis M. Crage.

Lutman, F. C. Tendon-transplantation technique for external-rectus paralysis. Amer. Jour. Ophth., 1946, v. 29, Jan., pp. 88-90.

Paton, R. T. Sight restoration through corneal grafting. Sight-Saving Rev., 1945, v. 15, Spring, p. 3.

The author discusses keratoplasty for the laity. The history and the nature of the operation, the causes of corneal opacities, the types of eyes which are operable, the results, and the method of preserving the donor eyes are described. The aims, hopes, and objectives of the newly formed Eye-Bank are discussed. The author estimates that of the 250,000 blind in the U.S., 10,000 to 15,000 could have their sight improved through keratoplasty.

Morris Kaplan.

Pickerill, H. P. **Method and appliance for grafting eye sockets.** Brit. Med. Jour., 1945, April 28, p. 596.

To avoid the almost insuperable difficulty of having a special eye made for every grafted socket, especially those following gunshot wounds, the author has devised a method for making a perforated acrylic mold of the socket. The mold is made from a cast slightly larger than an ordinary stock eye, and is made with two openings. One opening at the site of the pupil of the final prothesis serves to fix the peg which holds the mold in place while the underlying graft heals in the previously prepared orbital socket. Later the peg is removed and the socket is irrigated through the same opening. The second opening in the mold serves as a channel of escape for the irrigating fluid and secretions.

Francis M. Crage.

Sanders, N. W. **Treatment of a perforating corneal wound with penicillin and sulfadiazine.** Jour. Amer. Med. Assoc., 1945, v. 127, Feb. 17, p. 397.

The author describes a case of a perforating injury of the cornea which was seen after four days when a well-developed enophthalmitis was present. Huge doses of sulfadiazine and penicillin were given intramuscularly, topical-

ly, and subconjunctivally. After recovery the visual acuity was 5/200.

Morris Kaplan.

Schmelzer, Hans. **The problems of ocular tuberculosis and its treatment.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Jan., pp. 24-42. (See Section 17, Systemic diseases and parasites.)

Sedan, J. **Lutazol chemotherapy of trachoma.** Ann. d'Ocul., 1941, v. 177, no. 8, pp. 283-300.

Lutazol, a salt of acid para-sulfamido-phenyl-azosalicylate, was injected subconjunctivally in 7.5-grain doses for six injections. A preceding anesthetic injection of butylline or cocaine was used without adrenalin. Lutazol was also administered internally. Thirty grams were given in ten days. Three methods of administration were used: injection and ingestion, injection, and ingestion. The first method is preferred. The average duration of treatment was three weeks. Practically all stages of the disease were represented in patients treated, and all were inactive at the completion of the treatment.

Chas. A. Bahn.

Selinger, Elias. **Dermatitis of the lids from penicillin.** Jour. Amer. Med. Assoc., 1945, v. 127, June 9, p. 437.

In a case of contact dermatitis of the lids following instillation of a rather weak penicillin solution it was interesting to note the absence of reaction of the conjunctiva. Healing was prompt upon removal of the drug.

Morris Kaplan.

Simpson, D. **The cautery in plastic operations on eyelids.** Brit. Med. Jour., 1945, Sept. 29, p. 424.

The author uses the cautery for the correction of ectropion, entropion, sym-

blepharon, distichiasis, and ptosis. The treatment for these lid disorders is multiple puncture with a small, redhot point. The resultant scar tissue corrects the defect. Actual cautery of the hair follicles in trichiasis is recommended.

Morris Kaplan.

Thorpe, H. E. Nonmagnetic intraocular foreign bodies. *Jour. Amer. Med. Assoc.*, 1945, v. 127, Jan. 27, p. 197.

The author discusses methods of removing nonmagnetic bodies from all parts of the eyeball. A careful history and an examination of tools and metals used at the time of injury will usually determine whether the foreign body is magnetic. He urges the use of the X ray when there is any question of intraocular foreign body and highly recommends the Berman locator. The author describes in detail his preparation of the patient before surgery and his post-operative care, which routinely includes the use of foreign protein and sulfadiazine. He uses stenopeic spectacles after transcleral wounds posterior to the ora serrata. The use of the Thorpe ophthalmic endoscope for foreign bodies in the vitreous is described in detail. (Diagrams.) Morris Kaplan.

Tooke, F. T. Penicillin in ophthalmology. *Canadian Med. Assoc. Jour.*, 1945, v. 53, Oct., p. 373. (Round-table conference.)

A round-table discussion on clinical effects of penicillin in the eye is presented. The properties of the drug are described, and a list is given of those organisms which are affected by penicillin and those which are resistant to it. Noteworthy among the insensitive organisms is *Staphylococcus albus*. It is interesting to note that in ophthalmic diseases therapeutic response was

uniformly good, despite a wide variation in the dosages of the drug.

Morris Kaplan.

Townes, C. D. Surgical treatment of heterophoria. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1945, July-Aug., pp. 338-346.

Two hundred and eleven operations were performed upon 135 aviation cadets for the correction of disqualifying heterophorias. One hundred and one operations were performed on 66 patients with exophoria, 55 of whom obtained satisfactory results from a military standpoint. In exophoria the relative amounts of divergence excess and convergence insufficiency were found of little importance in determining the most desirable type of operation. Recession of the lateral rectus was preferred and performed on 35 patients. Eighty-three operations were performed on 51 patients with esophoria, 47 of whom obtained satisfactory results. Resection of the external rectus was most frequently performed because of divergence insufficiency. Twenty-seven operations were performed on 18 patients with hyperphoria, 15 of whom obtained satisfactory results. In eight of these, paresis of the superior rectus existed in one eye with overaction of the inferior oblique of the other eye. In these myectomy of the overacting inferior oblique was performed. Plain catgut no. 4-0 was preferred to chromic catgut of the same caliber because the latter failed to become absorbed in several eyes.

Chas. A. Bahn.

Vancea, P. Sulfa therapy in trachoma. *Ann. d'Ocul.*, 1941, v. 177, no. 8, pp. 300-312.

Fifty cases of trachoma were observed during five months and are reported statistically. All patients were

given sulfathiazole internally. The average dose was 100 grams. The patients were divided into five groups. Those in the first group were given only sulfathiazole internally, in the second sulfathiazole internally and a 5-percent sulfathiazole ointment locally, in the third only sulfathiazole ointment, in the fourth sulfathiazole by rectum, and in the fifth sulfathiazole ointment followed by conjunctival massage. In 20 of the patients slight bodily symptoms were observed from the internal use of the sulfathiazole. The author concludes that sulfa therapy is the most practical and rapid treatment for trachoma. The virus of trachoma was not found after four or five weeks.

Chas. A. Bahn.

3

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Bane, W. M. **An analysis of the changes in refraction (based on a study of the case histories of Dr. Edward Jackson).** Trans. Amer. Ophth. Soc., 1944, v. 42, pp. 399-410.

The author reviewed the records of 10,000 of Dr. Edward Jackson's patients who had repeated refractions for 10 years or longer. In hyperopic errors of refraction he found a marked tendency toward an increase in the spherical and cylindrical components. In myopic errors there was a slight tendency toward a decrease in the spherical component, with an increase in the cylindrical component. There was a marked tendency to an increase of the total myopia until the age of 40 years; after that age the trend was toward an increase in the hyperopia. In mixed astigmatism the trend was toward a decrease in the amount of astigmatism. (10 tables, bibliography.)

Carl D. F. Jensen.

Bannon, R. E. and Walsh, R. **Repeatability of keratometric readings.** Amer. Jour. Ophth., 1946, v. 29, Jan., pp. 76-85.

Berry, G. L. **Visual discomfort in eye workers due to glasses.** Jour. Oklahoma State Med. Assoc., 1945, v. 38, Sept., p. 361.

The author presents a plea for more accurate testing of the functions of the extraocular muscles and of accommodative power in routine refraction. He believes that properly placed prisms or decentered lenses should be used in many more spectacles. Numerous examples are given. Morris Kaplan.

Diaz-Caneja, Emilio. **Bicylindrical correction.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Jan., pp. 19-23.

The author discusses the biastigmatism of Marquez and affirms its accuracy. He states, however, that the method is complicated and requires reference to tables, which is inconvenient. He prefers a more direct method of refraction, using a frontofocometer.

J. Wesley McKinney.

Dejean, C., and Roux, N. **Bilateral contracture of accommodation by abuse of sulfonamides.** Bull. Soc. d'Ophth. de Paris, 1939, Oct.-Dec., pp. 582-584. (See Section 2, Therapeutics and operations.)

Fink, W. H. **Trial frame for young children.** Trans. Amer. Ophth. Soc., 1944, v. 42, pp. 397-398. (See Amer. Jour. Ophth., 1945, v. 28, p. 403.)

Goldmann, H. **Objective determination of visual acuity.** Ophthalmologica, 1943, v. 105, May, pp. 240-252.

A new method is offered for the objective determination of visual acuity

in malingerers. The test object consists of a plate which swings behind a window-shaped opening in a screen. The plate is covered by a coarse checkerboard pattern whereas the screen is a checkerboard which consists of much smaller squares. To an eye which cannot distinguish the squares in the coarse pattern, the plate and screen appear as a uniform gray surface and the swinging movement behind the window opening is not noticed. If the coarse pattern is perceived, its swinging motion will be noted and the eye will follow these oscillatory movements involuntarily. Max Hirschfelder.

Linneu Silva and Correa, C. A. *Transitory myopia from sulfanilamides*. Rev. Brasileira de Oft., 1945, v. 4, Sept., pp. 5-26.

After reviewing a number of cases from the literature, the authors record a personal case, with the usual history of rapid recovery after withdrawal of the drug. During the attack the patient's myopic error increased in the maximum meridian from 0.5 to 3.5D. (Bibliography.) W. H. Crisp.

Marquez, M. *Bi-astigmatism*. Ann. d'Ocul., 1941, v. 177, no. 11, pp. 415-425.

The derivation of the formula for the computation of spherocylindric equivalents of two cylinders at oblique axes is given. Illustrative cases are mentioned to show the potential advantages of obliquely crossed cylinders.

Chas. A. Bahn.

McFarland, R., Halperin, M., and Niven, J. *Visual thresholds as an index of the modification of the effects of anoxia by glucose*. Amer. Jour. Physiol., 1945, v. 144, Aug. 1, p. 378.

The measurement of differential in-

tensity thresholds for vision at low levels of brightness provides a sensitive and objective index of the impairment caused by anoxia. This test was applied to the study of the modification of this impairment by glucose. Three fasting subjects were used at simulated altitudes of 12,700 to 17,200 feet.

The ingestion of 50 grams of glucose during exposure to low oxygen tensions (simulated high altitude) resulted in a considerable decrease in the impairment due to anoxia. At a simulated altitude of 13,800 feet, the administration of glucose diminished the visual impairment of one subject to an amount corresponding to an altitude of only 8,000 feet. The "physiological altitude" was thus 42 percent lower than the actual altitude. In the other two subjects the lowering of the physiologic altitude was 25 percent and 48 percent, respectively.

The ingestion of glucose one-half hour before exposure to low oxygen tensions likewise prevented a large part of the impairment expected from anoxia.

Control experiments, in which a saccharin solution was given at simulated high altitude instead of glucose, showed no effects on the impairment caused by anoxia.

The administration of glucose to fasting subjects at a normal atmospheric oxygen tension resulted in no improvement of visual sensitivity. An improvement occurred only if visual sensitivity had first been impaired by anoxia.

The amount of improvement of visual sensitivity during anoxia after glucose administration, in relation to time, was approximately parallel to the blood-sugar curve during its rise and subsequent fall.

The increase in carbon-dioxide production after glucose ingestion lags behind the rise in blood sugar and declines considerably later than the fall in blood sugar. The "anti-anoxic" effect of glucose, therefore, seems to depend directly on the blood-sugar level rather than on the secondary increase in carbon-dioxide production.

Theodore M. Shapira.

Porter, A., and Godding, E. W. Dark-adaptation studies in skin disease. *Brit. Med. Jour.*, 1945, June 16, p. 840.

Dark adaptation was tested in 103 patients with nonparasitic skin diseases and in 101 normal controls. There was no significant difference between the two groups. One patient with pityriasis rubra pilaris had normal dark-adaptation after vitamin A therapy.

Francis M. Crage.

Woods, A. C. Myopia therapy by visual training. *Amer. Jour. Ophth.*, 1946, v. 29, Jan., pp. 28-57.

OCULAR MOVEMENTS

Redslob, E., and Delbos, R. Superior oblique paresis of sinus origin. *Ann. d'Ocul.*, 1941, v. 172, no. 10, pp. 371-378.

A man, 30 years of age, suddenly developed a crossed diplopia. The vertical separation of images was greatest in the lower left quadrant and the image of the right eye was the lower. After radiograms of the sinuses had been taken the patient was placed on appropriate treatment, the details of which are not mentioned. Immediately recovery followed. The causation and pathology are discussed at some length.

Chas. A. Bahn.

5

CONJUNCTIVA

Bhalerao, C. K. Trachoma. *Antiseptic*, 1945, v. 42, Sept., p. 491.

A short general discussion of trachoma is presented for the general practitioner of India. The author prefers the use of silver nitrate and copper sulfate and believes that sulfonamides have no therapeutic effect on the disease itself.

Morris Kaplan.

Guerry, Du Pont, III. Oculoglandular tularemia. *Virginia Med. Monthly*, 1945, July, p. 295.

Ocular tularemia in a child of 7 years is described. It closely resembled vaccinal conjunctivitis when first seen, but when severe systemic reactions developed, routine agglutinations revealed the true diagnosis. The differential diagnosis is discussed.

Morris Kaplan.

Kahaner, J. R. Exogenous meningococcic conjunctivitis. *New York State Jour. Med.*, 1945, v. 45, Aug. 1, p. 1687.

This case of exogenous meningococcic ophthalmia is presented in order to stress the need for complete cultural and serologic differentiation of the species of *Neisseria* which may be responsible for a suppurative conjunctivitis. A diagnosis of gonorrheal ophthalmia based only on the clinical characteristics of the lesion and the presence and the laboratory report of gram-negative intracellular and extracellular diplococci in a smear may be erroneous.

Theodore M. Shapira.

Morax, P., and Costil, L. Keratoconjunctivitis, phlyctenular and tuberculous infections. *Ann. d'Ocul.*, 1941, v. 177, no. 12, pp. 435-446.

Thirty patients were studied in de-

tail. In eight, the morning gastric content with swallowed expectoration was found to contain tubercle bacilli as proved by staining and positive guinea-pig inoculation. Ages ranged between 2 years and 20. In one third of the cases tuberculosis was present in the immediate family or in contacts. A tuberculous skin reaction was positive in all. Of 13 patients examined radiologically, 10 had evidence of old thoracic lesions. Of the 30 patients, 19 were female and 11 male. The authors conclude that phlyctenular disease should not be treated as a purely local condition. Search should be made among the immediate family or contacts for tuberculosis, and some of the patients should be managed according to a modification of the regime designed for the tuberculous.

Chas. A. Bahn.

Reid, J. J., and Anigstein, L. **Keratoconjunctivitis in cattle on the Gulf Coast of Texas.** Texas Reports on Biol. and Med., 1945, v. 3, Summer, p. 187.

Infectious keratoconjunctivitis of North American cattle is endemic and frequently becomes epidemic. Fifty to 70 percent of herds may become infected, which causes much economic waste. The symptoms are similar to those of the disease in man though the disease is more severe in cattle and much oftener leads to complete opacification of the cornea. It is highly contagious. Laboratory studies revealed a hemolytic diplobacillus as the specific etiologic agent. The disease is most probably a systemic infection which confers immunity. Prevention by means of a specific bacterial vaccine is being investigated.

Morris Kaplan.

plantation. Canadian Med. Assoc. Jour., 1945, v. 53, Dec., p. 548.

The author describes a corneal transplantation combined with cataract extraction after which the patient's visual acuity was 1/60. He calls attention to the value of the operation for sight saving and urges the establishment of an eye bank.

Morris Kaplan.

Friede, R. **The need for a protective knife in penetrating keratoplasty.** Klin. M. f. Augenh., 1942, v. 108, Sept.-Oct., p. 570.

Friede believes that the insertion of a metal or ivory spatula into the anterior chamber during penetrating keratoplasty is not only unnecessary but dangerous. If it seems necessary to protect the deeper structures of the eye, it is wiser to use small circular plates, adapted exactly to the size of the corneal hole, which can be inserted in it temporarily. The upper part of the plate contains four small holes and four notches intended to receive sutures to keep it firmly in place. The upper edge overhangs the plate itself to prevent it from falling into the anterior chamber. It can be left in place for hours or even days in cases where the donor's flap has been lost or a new flap is not available immediately. (3 figures.)

F. Nelson.

Halbertsma, K. T. A. **Papilloma of the cornea.** Ophthalmologica, 1943, v. 105, June, pp. 299-307.

The author describes a case of papilloma of the cornea of fifty years' duration. The condition is rare, and only 100 cases have been previously reported. It is very difficult to differentiate clinically, and sometimes even histologically, between papilloma and epithelioma. The pathologic differences are discussed in the article.

Max Hirschfelder.

Kronenberg, B. Multiple tuberculous nodules of the episclera. *Amer. Jour. Ophth.*, 1946, v. 29, Jan., pp. 86-88.

Magitot, A. Mooren's ulcer of the cornea treated by Moretti's suture. *Bull. Soc. d'Ophth. de Paris*, 1939, Oct.-Dec., pp. 574-575.

A typical case of Mooren's corneal ulcer is described. After various forms of therapy had failed, the author applied a silk suture around the cornea as suggested by Moretti. Starting on the temporal side, the needle is directed under the conjunctiva 2 to 3 mm. from the limbus and both suture ends are finally brought back on the cheek. The result in this instance was excellent, with early cicatrization and healing of the ulcer.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Blegvad, Olaf. Iridocyclitis and disease of the joints in children. *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 219-236.

The author reports six cases of this syndrome and reviews five which have been reported. The disease attacks children from two to ten years of age. The joint disease may be a chronic juvenile infectious peri-arthritis or have all the symptoms of Still's disease, with recurrent febrile periods, progressive polyarthritis, polyadenitis, anemia, enlargement of the spleen, and muscular atrophy. The eye and joint symptoms are usually of equal severity. The iridocyclitis has no distinctive features. When the illness is mild good vision is recovered but often a band-shaped keratitis remains. Severe inflammations may end in occlusion of the pupil, iris bombé, complicated cataract, and blindness. Of the author's six patients four

recovered with good vision. One had 3/18 vision in one eye, and one had 2/36 in the right eye and 6/24 in the left. (References.) Ray K. Daily.

Brueckner, R. Eye and cholinesterase (first report). *Ophthalmologica*, 1943, v. 105, Jan., pp. 37-49.

To investigate the importance of acetylcholine and similar substances in the chemical reactions that are associated with the transmission of nervous impulses, Brueckner studied the presence of cholinesterase in the eye. This substance is a ferment which inhibits the effect of acetylcholine. The fluids of the eyeball as well as tissue extracts can be tested for the presence of cholinesterase by bringing them in contact with acetylcholine *in vitro*. Cholinesterase splits acetylcholine into choline and acetic acid. The latter liberates carbon dioxide from a solution of sodium bicarbonate. The quantity of carbon dioxide that is liberated can be measured manometrically and is an index of the quantity of the esterase. Using this method on eyes of cattle and horses the author found that cholinesterase is always present in the aqueous humor. Its concentration relative to the total proteins is greater in the aqueous than in the blood serum; therefore he assumes that some of it comes from other sources than the blood. The cholinesterase content of the vitreous in the eyes of cattle and swine is very considerably higher than that of the aqueous. The concentration varies in different parts of the vitreous. It is probable that the esterase in the vitreous has its origin in the retina. Physostigmine inhibits the action of the ferment. (Literature.)

Max Hirschfelder.

Brueckner, R. Eye and cholinester-

ase (second report). *Ophthalmologica*, 1943, v. 106, Oct., pp. 200-212.

The presence and quantity of cholinesterase in different parts of the uveal tract of the eyes of cows were determined by the manometric method described by the author in a previous report. The greatest quantity of cholinesterase was found in the pupillary part of the iris; the pigment epithelium of the iris and the retina contained about half as much. Decreasing amounts were found in the intermediate and ciliary part of the iris and in the equator of the choroid. Still less was found elsewhere in the choroid, the base of the ciliary body, and, especially, the pigment epithelium of the retina. These findings show that cholinesterase is increased in the sites where acetylcholine is formed. This is also true for the intraocular muscles which are innervated by the oculomotor nerve.

Delord, Emile. **A new syndrome: recurrent iritis, vitreous hemorrhages, recurrent ulcers of the mouth and of the genital organs.** *Ann. d'Ocul.*, 1941, v. 172, no. 10, pp. 366-371.

A man 55 years of age had this syndrome for four years, with an ultimate visual acuity of 4/10 in the right eye and 2/10 in the left eye. The possibilities of syphilis, tuberculosis, focal infection with staphylococcus, and allergy are discussed and dismissed. Five somewhat similar cases in the literature are briefly reviewed.

Chas. A. Bahn.

Esbjerg, H. O. **A case of uveoparotid fever attended by erythema nodosum and pulmonary changes.** *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 286-292.

A case of typical uveoparotid fever associated with erythema nodosum and

sarcoid of Boeck in the lungs in a woman 25 years of age is reported. The disease began with joint manifestation and cutaneous eruptions; two weeks later the patient developed bilateral swelling of the parotid glands; a peripheral paresis of the left side of the face appeared in two days, and a month later she was found to have a bilateral iridocyclitis. Roentgenographic studies of the lungs suggested Boeck's sarcoid. The tuberculin test was negative. The author reviews the investigations on the etiology of uveoparotid fever, and concludes that it is a manifestation of the sarcoid of Boeck. (References.)

Foss, Bjorn. **Bilateral recurrent hypopyon-uveitis (Behcet's syndrome).** *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 292-329.

A review of the literature reveals that this disease predominantly attacks men 5 to 40 years of age, and in all but one of the patients was accompanied by diseases of the skin or oral mucous membrane. In more recent publications bilateral recurrent hypopyon-uveitis is reported as a part of Behcet's trisymptomatic syndrome, associated with a general cutaneous hypersensitivity, especially to staphylococcus vaccine. The etiology is unknown; it may be tuberculosis, focal infection, an endocrine disturbance, avitaminosis, or a virus infection. It is not known whether the eye lesion is secondary to a primary disease of the skin and mucous membrane or whether there is simultaneous involvement of the other tissues and of the eye by an unknown virus. The hypopyon-uveitis leads to total blindness within a few years. No fatalities are on record; neither is there a cure.

Two cases are reported in detail. One occurred in a seaman, 30 years of age, who had recurrent acute attacks of blurred vision with hypopyon; the hypopyon cleared up rapidly, but the vitreous did not clear between the attacks. Vision failed gradually, and a relative scotoma and macular changes developed early; later, the fields became contracted concentrically, and the optic papilla became atrophic, with thin partially obliterated vessels. Late in the disease the attacks of uveitis were associated with ulcers of the mouth, and finally ulcers on the genitalia appeared. All forms of therapy were futile, and the patient became blind. The second patient was a man of 35 years, who developed chills, fever, malaise, a purulent eruption on the legs, and foggy vision a few days after he had waded through a stream. Since then he has had repeated attacks of fever, pain in the muscles and joints, ulcers and abscesses of the skin, and ulcers in the mouth and scrotum. Vision became blurred a few days after the onset of each attack. Within two years his visual acuity was reduced to the ability to count fingers at one meter from the eyes. During the next two years the patient had 10 attacks of hypopyon-uveitis in each eye. At the end of this time the right eye was soft and shrunken and had an opaque lens. The left eye was soft but the fundus was visible; the optic disc was atrophic, and the vessels thin and partially obliterated. In the course of the disease, fleeting nodules which resembled pustules appeared on the iris and left small holes therein. This patient was hypersensitive to staphylococcus vaccine; minute subcutaneous doses caused enormous infiltrations followed by attacks of uveitis. In the course of therapy, blood transfusions, while powerless to halt

the progress of the disease, produced immediate improvement and some clearing of the media. (References.)

Ray K. Daily.

Manschot, W. A. **Expulsive hemorrhage. Two remarkable anatomic discoveries.** *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 237-253.

Two cases of expulsive hemorrhage after cataract extraction are reported. The histopathologic examination of the enucleated eyes revealed unusual data which might have escaped discovery but for the examination of serial sections. In the first case, the hemorrhage occurred immediately after the precipitous delivery of the lens as soon as its capsule was opened. The microscopic sections revealed the presence of an angioma racemosum around a vortex vein. The author believes this to be the first case of this form of intraocular angioma to be reported.

The expulsive hemorrhage in the second patient occurred on the second day after an uneventful extraction. The microscopic sections revealed an extensive necrosis of the walls of some ciliary arteries with thrombosis of a considerable area. In addition there were necrotic choroidal vessels which could have produced the hemorrhage. There was evidence of chronic glaucomatous change in the anterior uveal tissue, which suggests that glaucoma might have been the cause of the necrosis of the ciliary arteries. (15 photomicrographs, references.)

Ray K. Daily.

McGregor, I. S. **Segmental movement of the pupil.** *Brit. Med. Jour.*, 1945, May 5, p. 629.

This motion takes the form of a twitch of the sphincter or pupillary margin of the iris. The twitch may in-

volve one part of the margin and then another, or there may be synchronous twitches in separate parts of the sphincter, called concertinalike movement. Twitching in the latter form is much less common than are single, partial, or double synchronous forms. This sign may be seen in eyes which have no pupillary response to light. It has been observed in luetic optic atrophy, quinine amblyopia, posttraumatic sphincter paralysis, and in Leber's disease. A monocular loupe or low-power microscope suffices for recognition in most cases. The condition which the author calls pupillary unrest may occur whenever there is a sufficiently severe disturbance of the afferent or efferent nerve paths to the iris sphincter. Peripherally acting mydriatics which inhibit the choline flux can produce it. Weakness of conduction in the nerve path and variability in the amount of the impulse which reaches the sphincter help to explain the trouble. The sign has no localizing value.

Schalig, G. A. Koyangi's disease with report of one case of unilateral uveitis, herpetic keratitis, dysacusis, alopecia, poliosis, and vertigo. *Klin. M. f. Augenh.*, 1942, Sept.-Oct., v. 108, p. 584.

Koyangi's disease is a very rare symptom complex of unknown etiology. The author's patient was a man, aged 47 years, whose left eye became almost blind within four days as a result of acute anterior uveitis and keratitis. A spotty depigmentation of the hair of the scalp, eyebrows, and lashes as well as of the skin of the head and part of the neck was observed. There was also a partial loss of hair in these regions and an almost complete loss of the beard. This process had started

about one year previously and was accompanied by a complete loss of libido. Tinnitus and vertigo began two weeks before the first examination. The left ear became deaf at the same time the left eye became blind. Serologic, neurologic and otologic examinations were essentially negative. Within two weeks the patient's condition improved. The left eye became almost normal. The hair began to grow and regained its pigment. The sexual functions became normal. There were three recurrences in the 12 years after the first attack; each attack was followed by almost complete recovery. In this case the left eye alone was involved in each attack, whereas both eyes are usually affected. The essential manifestations of the 39 reported cases of Koyangi's disease are presented in tabular form. (Bibliography.)

GLAUCOMA AND OCULAR TENSION

Bloomfield, Sylvan. Parasympathomimetic effect of aqueous humor in human eyes with and without chronic simple glaucoma. *Proc. Soc. Exper. Biol. and Med.*, 1945, v. 60, Nov., p. 293.

Aqueous humor was withdrawn from eyes which had been exposed to eserine and strong light. Seven eyes had chronic simple glaucoma and 10 had no glaucoma. These fluids were perfused through isolated hearts of frogs. The aqueous humor from normal eyes induced reactions exactly similar to those of acetylcholine whereas the glaucomatous fluid did not. Apparently a parasympathomimetic substance is present in normal eyes but is absent from eyes with chronic glaucoma.

Morris Kaplan.

Cramer, F. K. Cyclodiathermy as an antiglaucomatous operation. - *Ophth.*

Ibero Amer., 1945, v. 6, no. 4, pp. 349-373 (in Spanish), and pp. 374-385 (in English).

The author made a series of experiments on rabbits as to the action of Vogt's method of penetrating cyclodiathermy and also of the flat method of cyclodiathermy used by Weve and by Albaugh and Dunphy.

Cramer concludes that the hypotensive effect of diathermy is practically the same for both techniques. He favors flat cauterization as being less traumatizing.

The hypotensive effect appeared to vary more with the intensity of the cauterization than with the extent of the surface cauterized. Cauterization of one fourth of the circumference was adequate to produce hypotension. Changes in the ciliary body varied according to intensity and extent of cauterization. Changes in the transparent media were not experienced, so that the proceeding could be employed not only in hemorrhagic and absolute glaucoma but also in other clinical forms. (9 figures, 4 photomicrographs, references.)

W. H. Crisp.

Gradle, H. S. A glaucoma clinic. Ophth. Ibero Amer., 1945, v. 7, no. 1, pp. 1-5 (in Spanish), and pp. 5-9 (in English).

The author describes the working of the glaucoma clinic which is attached to the Illinois Eye and Ear Infirmary. The management of the clinic is in the hands of an ophthalmologist and a full-time resident, with the assistance of a stenographer. The Social Service of the clinic is made responsible for seeing that the patient returns to the Infirmary at proper intervals for examination. A study of the visual fields of patients who have been under treatment more than two years indicates that 70

percent of those with normal visual fields have suffered no loss whatever, 16 percent show some change, and 14 percent have lost visual fields completely. About 147 per thousand of the patients remain industrially blind. The clinic now has on record about 1,760 cases, this number being increased by 20 to 30 each month. The living conditions of the patients are studied by the Social Service, and improved as far as possible. Glaucoma is the cause of 15 to 20 percent of all the cases of blindness in the United States. Ten years ago, an analysis of the cases of glaucoma seen at the Illinois Eye and Ear Infirmary in previous years showed that these patients stayed under observation less than two years and were never seen again.

W. H. Crisp.

Radnot, Magda. The anterior lobe of the hypophysis and the intraocular pressure. Ophthalmologica, 1943, v. 106, Oct., pp. 182-188.

The author found that the extract of the anterior lobe of the pituitary gland reduces the intraocular pressure. Large and small doses have the same effect. In three patients who were given the extract for dystrophia adiposo-genitalis a similar effect was noted. In animals which were subjected to unilateral sympathectomy a hypotension after injection with the hormone was of shorter duration on the sympathectomized side; whereas the hypotension lasted longer in the other eye than in normal animals. Sympathectomy alone had no effect on the intraocular pressure.

Max Hirschfelder.

Redslob, E. Glaucoma without hypertension and glaucomatous excavation. Ann. d'Ocul., 1941, v. 177, no. 9, pp. 323-340.

Structurally eyes vary greatly in

their reaction to intraocular pressure. A woman 62 years of age, whose visual acuity in the right eye and left eye was 20/50 and 20/40, respectively, and who has a 3D. overhanging excavation of the disc of the left eye was observed for eight months. At no time did the intraocular pressure exceed 20 mm. Hg in either eye irrespective of the use of mydriatics. The excavation of the disc was attributed to cavernous degenerative changes in the optic nerve in and behind the disc which diminish the resistance of the lamina cribrosa to tension. This may be associated with slight inflammatory reactions. The visual fields were essentially those of glaucoma. (31 references.)

Chas. A. Bahn.

Vidal, F., and Malbran, J. L. **Stelectomy and neurovegetative drugs.** *Ophth. Ibero Amer.*, 1944, v. 6, no. 3, pp. 257-270.

Ephedrine sulfate, 5 percent, does not affect intraocular pressure after stelectomy, causes less mydriasis after stelectomy, has equal action whether the stelectomy is recent or old. Adrenalin does not change the tension, and is only active after old stelectomies. Benzedrine sulfate, 0.25 percent, in normal and stelectomized eyes, causes less mydriasis after stelectomy.

W. H. Crisp.

Zeeman, W. P. C. **Two cases of secondary glaucoma with histologic findings.** *Ophthalmologica*, 1943, v. 106, Sept., pp. 136-142.

Hyperature cataracts led to acute inflammatory glaucoma in two patients. The enucleated eyes showed an edema of the optic nerve head and many swollen cells in the chamber angle, the spaces of Fontana, and in the iris tissue. Typical inflammatory infiltrations were lacking. The author interprets the

findings as signs of an abacterial inflammation of toxic origin due to deterioration of the lens substance. (References.)

CRYSTALLINE LENS

Altmann, F., and Dingmann, A. **Congenital deafness and cataract following rubella in the mother.** *Arch. of Otolaryng.*, 1945, v. 42, July, p. 51.

A case of congenital deafness and cataract in a child whose mother had had rubella during pregnancy is described.

According to Swan and his co-workers, all children of mothers who have rubella during the first two months of pregnancy are congenitally defective, and one half of the children will be defective if the disease is acquired during the third month of pregnancy. If the disease occurs after the third month congenital defects occur only occasionally.

Rubella is a serious disease during early pregnancy and gives rise to many practical problems. Erickson makes the following suggestions: girls should not be allowed to pass through childhood without having contracted rubella—a deliberate exposure at an opportune time would be deemed wise; rubella convalescent serum should be given to all women who are in the early stages of pregnancy and have not had rubella, particularly after exposure or during an epidemic; the justification for therapeutic abortion if rubella occurs during the first two months of pregnancy should be debated.

Theodore M. Shapira.

Cibis, P. **Cataract in neurodermitis disseminata.** *Klin. M. f. Augenh.*, 1942, v. 108, May-June, p. 281.

Neurodermitis is a dermatosis and is also variously termed eczema num-

mulare, eczema en plaques, dermatitis lichenoides pruriens. It is characterized by chronic recurrent paroxysmal pruritis, thickening of the skin, and coarseness of the skin folds. It may be limited to small areas or be widespread. Exacerbations during fall and winter occur. This skin disease is often accompanied by juvenile cataract in the form of a disc-shaped opacity at the anterior pole of the lens. It has been assumed that disturbances of internal secretion are responsible for the development of this skin disease as well as of the cataracts. The skin symptoms can sometimes be relieved by thyroid medication, but the cataract does not regress. Heredity seems to play an important part.

The report of two cases: (1) In a female of 39 years the dermatosis started after bronchitis when she was four or five weeks old. Cataracts developed at the age of 32 years and one of them was extracted successfully. Adequate clinical and laboratory studies revealed the absence of disturbances of metabolism and endocrine functions. (2) A male of 44 years suffered from "chronic eczema" since he was ten. Neurodermatosis had been diagnosed previously. A cataract in the right eye was diagnosed at the age of 36 years and was removed surgically one year later, but a dense pupillary membrane and secondary glaucoma developed. The glaucoma was controlled by miotics. In the left eye a subcapsular cataract in the posterior cortex was extracted extracapsularly. Here also glaucoma followed, necessitating cyclodialysis and miotics. There was no evidence of disturbed metabolism. (5 photographs, bibliography.)

F. Nelson.

Dunnington, J. H., Locatcher-Khorazo, D. Value of cultures before operation for cataract. *Arch. of Ophth.*, 1945, v. 34, Sept., pp. 215-219.

A study of a series of 2,508 cataract extractions was made to determine the value of preoperative cultures in the prognosis of postoperative infections and the influence of chemotherapy.

For the past eight years cultures of the eyes of patients admitted for cataract extraction have been examined for their bacterial flora. The purpose of this study was to determine whether any particular microorganisms were responsible for postoperative infections. More recently these bacteriologic studies have been extended to aid in the evaluation of preoperative prophylactic chemotherapy.

A detailed table is given of the various organisms found. *Staphylococcus albus* was encountered in 1,705 cases; pathogenic *Staphylococcus aureus* in 529 cases, which was defined by the fermentation of mannitol and the production of coagulase.

The authors' conclusions are that postoperative infections were due in the great majority of cases to pathogenic *Staphylococcus aureus*.

Postoperative infections observed were independent of the type of operation.

Of 730 cases in which no preoperative cultures were made and the preoperative treatment consisted of the instillation of 25-percent solution of protein silver three or four times in the twenty-four hours preceding operation, postoperative infection occurred in 13.

In 663 cases in which penicillin ointment (1,000 to 2,000 Oxford units), or sodium sulfathiazole ointment, 5 percent, was used preoperatively, no infections occurred.

In 104 cases in which, because of known pathogenic organisms, operation was delayed until treatment with penicillin or sulfathiazole had been applied, no infections occurred.

This study indicates that preopera-

tive cultures should be made on admission in every case in which cataract extraction is to be done, with a view to prophylactic treatment.

Duverger, C., and Bregeat, P. **Cataract and chronic glaucoma.** Arch. d'Opht., 1945, v. 5, no. 1, p. 3. (See Section 8, Glaucoma and ocular tension.)

Kötz, H. **A statistical study of hemorrhage after operations for senile cataracts.** Klin. M. f. Augenh., 1942, v. 108, May-June, p. 291. (See Section 2, Therapeutics and operations.)

Lindner, K. **Cataract operations, old and new methods.** Klin. M. f. Augenh., 1942, v. 108, Sept.-Oct., p. 567.

Lindner briefly summarizes the development of cataract surgery during the last four decades. He advocates routine subconjunctival injection of a small amount of a 3-percent cocaine solution around the cornea, which produces a complete and persistent anesthesia and mydriasis. He uses a retrobulbar injection of novocaine. Instead of one peripheral iridectomy he makes two, one on each side of a suture which he applies before he makes the incision with the cataract knife. Lindner prefers the sliding maneuver to the tumbling of the lens because the latter leads to more frequent vitreous prolapse. He irrigates the anterior chamber with warm Ringer's solution. When the lens capsule is very tense he pricks it and allows some cortex to escape so that the capsule may be grasped more easily with the forceps. F. Nelson.

McGraw, James L. **Marfan's syndrome with unusual complications.** Arch. of Ophth., 1945, v. 34, Aug., pp.

112-113. (See Section 17, Systemic diseases and parasites.)

Papolczy, F. **Changes in cataract operation with round pupil.** Klin. M. f. Augenh., 1942, v. 108, Sept.-Oct., p. 567.

To avoid incarceration or prolapse of the iris caused by rupture of the wound, corneoscleral suturing is important in extractions with round pupil. The author prefers Imre's method, which he has modified slightly. After a bridge suture has been placed in the tendon of the superior rectus muscle, a silk suture is inserted through the conjunctiva into the episcleral tissue, 2½ mm. above the limbus. Section is made with a Graefe knife, as usual, with formation of a conjunctival flap, except that the latter is cautiously withdrawn from the wound before the incision is completed. The bulbar conjunctiva is cut with a pair of curved scissors and dissected from the episcleral tissue to form a semilunar flap. After severance of the small corneoscleral bridge, the flap is put back on the cornea. Papolczy performs peripheral iridectomy and extracts the lens intracapsularly. The suture is knotted three times and left in place for 10 days. F. Nelson.

Rados, A. **Vitamin C saturation and senile cataract.** Arch. of Ophth., 1945, v. 34, Sept., pp. 202-209.

Investigators are unanimous in the opinion that the amount of vitamin C present in the lens and in the aqueous is much higher than in other tissues or in the blood. However, there is a wide discrepancy in the explanations of how this high concentration of vitamin C is produced. Vitamin C diminishes as the lens becomes progressively opaque and disappears when the opacification is complete.

The lens, being devoid of a blood supply, is especially dependent for its normal metabolism on intracellular substances which form oxidation-reduction systems.

The important observation that the vitamin-C content of the normal lens diminishes in proportion to the formation of cataract to values approaching zero and, also, that aging of the lens similarly results in decrease of the vitamin-C content, seems to substantiate the belief that vitamin C is of extreme importance for the respiration of lens tissue.

Vogt, on the other hand, doubts that hypovitaminosis C is the cause of cataract. He believes that senile cataract develops irretrievably and inevitably from the genetic anlage.

The author says, however, that one of the most common misconceptions of genetic laws seems to be the conclusion that a character which is conditioned by heredity cannot be modified by environment. Hence, even if the concept of the hereditary basis of senile cataract were to be accepted, it would not exclude the possibility of environmental influences, of which metabolism, directly or indirectly (as vitamin C influencing the adrenal cortex), is only one of the numerous factors.

After discussing the literature and his experiments, Rados concludes that the saturation test is the most accurate index of vitamin-C deficiency. Of 200 unselected patients with cataract, 135 revealed a saturation level of the body for vitamin C.

The remainder of the series, 65 patients, showed a low level of vitamin-C excretion after intravenous administration of ascorbic acid. In 35 patients the deficiency was mild, and in 33 patients it was so pronounced as to represent a general deficiency.

There is not sufficient evidence to indicate that vitamin-C deficiency contributes to the formation of cataract. The vitamin-C deficiency of some of the cataractous patients seems to be the natural result of the vitamin-C deficiency of old age. R. W. Danielson.

Torres Estrada, Antonio. Some modifications in suture and technique of the cataract operation. *Bol. del Hosp. Oft. de Nuestra Señora de la Luz*, 1945, v. 3, May-Aug., pp. 50-67.

The author reviews and illustrates a number of sutures, including one which he describes as that of Suarez de Mendoza but which seems to have a good deal of resemblance to a suture known in the United States as that of McLean. The 18-page article, with its 18 illustrations, restates the author's complete technique for cataract extraction.

W. H. Crisp.

Weber, H. Thermic circulation in the lens. *Klin. M. f. Augenh.*, 1942, v. 108, Jan.-Feb., p. 99.

The vertical convection current in the anterior chamber is a well-known normal phenomenon which is caused by the difference of the temperature in the anterior and posterior parts of the chamber. Weber reports the case of a male of 45 years in whose right eye an extracapsular-cataract extraction had been followed by the development of a dense secondary membrane which gradually transformed into a sac shaped like the original lens and filled with fluid and cortical detritus. With increasing clarification of the fluid a definite slow thermic circulation was observed which gradually became more rapid so that eventually the current flowed as fast as that in the anterior chamber. An attempt to extract the lenticular sac in toto was unsuccessful.

ful. The capsule ruptured and some milky fluid escaped, some vitreous prolapsed. Vision became 5/5. (References.) F. Nelson.

A case of bilateral disciform degeneration of the macula of the senile type is reported. The literature on the subject is briefly discussed. (4 illustrations, bibliography.) Plinio Montalván.

Benavides, E. S. **A contribution to the biomicroscopy of the normal vitreous.** Arch. de la Soc. Hisp.-Amer., 1944, v. 4, Nov.-Dec., p. 1082.

The conclusions based on an examination of 300 normal eyes are: (1) The vitreous is a colloid in the form of a hydrogel with a density which increases from the center to the periphery and a structure which is as varied as fingerprints. The appearance of the vitreous may be fibrillar, cellular, or tufted. A loose fibrillar structure is characteristic of colloidal maturity and is more frequent in the second half of life. (2) The arrangement in light and dark bands, which is seen with the biomicroscope, is an illusion due to the illumination and direction of observation modified by the refracting ocular media. There are no vacant areas in the vitreous and no bands which rise and fall. (3) The retrolental space does not exist, and the surface of the vitreous is in intimate contact with the posterior surface of the lens. (4) Normally Cloquet's canal is not visible biomicroscopically, and Ida Mann's theory relative to this structure is not supported

by mathematical calculation of its size. (5) The arciform line of Vogt is actually the external limit of an undulating circular surface, probably related to Cloquet's canal in fetal life. The embryonal remains of the hyaloid artery originate at some point on this surface.

(6) The changes which the vitreous undergoes with the years affect its luminosity, so that there is a difference between juvenile, adult, and senile vitreous. Generally the luminosity depends on the quantity of uveal pigment, which is more luminous in blue than in dark eyes. It becomes less luminous with age and since luminosity diminishes with the acidity of a colloid, this decreasing luminosity indicates an increasing acidity. (7) It is necessary to revise the index of refraction of the vitreous. The reasons for such diseases as myopia, glaucoma, and retinal detachment should be sought in these colloidal transformations. (Numerous illustrations.) Ray K. Daily.

Borley, W. E., McAlester, A. W. III, and Lower, R. A. **Central macular chorioretinitis in Naval personnel.** U. S. Naval Med. Bull., 1945, v. 45, Sept., p. 511.

Laboratory studies were made on a group of 31 young adult males who had central macular areas of chorioretinitis. A typical case is described. All ordinary and routine laboratory tests were negative. Spinal fluid from the patients was injected into the eyes, brains, and peritoneal cavities of guinea pigs. Control injections were also made with normal spinal fluid. The brain and peritoneal injections were essentially negative whereas all the eye injections produced pathologic lesions. The affected eyes became the site of acute iridocyclitis which appeared within a day and

remained active for two to three weeks; the lenses became opaque and the vitreous humor became cloudy. In the control animals no eye symptoms developed. These results suggest a possible involvement of the cranial nerves.

Morris Kaplan.

Broendstrup, Poul. **Retinal detachment as a hereditary disease.** *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 272-280.

A review of the literature is followed by a report of the author's own material. The history of one family reveals three cases of retinal detachment in three successive generations, at the age of 50, 19, and 10 years, respectively, and probably a fourth case in an earlier generation. In a second family one of two sisters had a retinal detachment in her myopic right eye at the age of 14 years, and the other, who was emmetropic, in the left eye at the age of 25 years. In the third family a brother and a sister with congenital ocular anomalies developed retinal detachment: the sister at the age of 13 years after an injury, and the brother at the age of 15 years.

The author concludes that retinal detachment can be an inherited disease and that no significance can be attributed to axial myopia. Infantile and senile retinal detachments occur predominantly in nonmyopic eyes and retinal detachments in myopic eyes occur in the intermediate years. Myopia predisposes to retinal detachment because the pathologic changes that are conducive to retinal detachment occur with greater frequency and at an earlier age in the myopic than in other people. Inherited myopia and degeneration are produced by two adjacent genes which are not always associated. If, in my-

opia, the second gene is absent, no retinal detachment need occur regardless of the degree of myopia. Trauma is not as significant a factor as it is assumed to be. It is astounding to observe the severe traumatism which myopic eyes tolerate without developing retinal detachment. It is doubtful if detachment should be attributed to a trauma in eyes in which there is no external evidence of injury. (References.)

Godfrey, E. W., Schenck, H. P., and Silcox, L. E. **Response of the retina to the direct roentgen beam.** *Radiology*, 1945, v. 44, March, pp. 229-236.

The writers used the method of Pirie for determining the extent of retinal damage and the possible presence of opaque foreign bodies in 74 eyes injured in battle. The findings in 52 of them are tabulated. The authors were able to predict an intact retina in nine patients in whom ophthalmoscopic observation was impossible, and in 15 instances a diagnosis of retinal destruction was made. They discuss the sensitivity of the retina to Xrays and believe that the phenomenon may be valuable in assessing the condition of the retina. Occasionally an intraocular foreign body may be detected by the patient when the X-ray beam traverses its site to reach the intact retina. (Bibliography.) Melchior Lombardo.

Heath, P., and Zuelzer, W. W. **Toxoplasmosis (report of eye findings in infant twins).** *Trans. Amer. Ophth. Soc.*, 1944, v. 42, pp. 119-130.

The authors describe two premature infants with toxoplasmosis. There is a description of pathologic preparations of the eye of the deceased infant as well as of the ophthalmoscopic findings in

the surviving identical twin. The chorioretinal lesion in the acute stage was a slightly elevated, yellowish-white, well-demarcated lesion. The old healed lesions simulate coloboma. The mother and surviving twin reacted positively when the blood serum was tested for neutralizing antibodies of toxoplasma. (5 photomicrographs, bibliography.)
Carl D. F. Jensen.

Longhena, Luisa. The retroretinal fluid in retinal detachment. *Ophthalmologica*, 1943, v. 106, July-Aug., pp. 27-40 and 80-92.

After reviewing the literature dealing with the physio-chemical composition of the retroretinal fluid in retinal detachments, the author adds her own investigations based on the study of 30 cases. The color, reaction, transparency, refractive index, protein content, albumin-globulin relation, chloride content, and sugar content were determined. She concludes that the retroretinal fluid is primarily an exudate which in the earlier stages is diluted by the influx of vitreous. In older detachments the fluid has a higher protein content due to disintegration of the retinal cells. Longhena stresses the fact that the retroretinal fluid has a different composition from that of the vitreous and therefore cannot be identified with it. The theory of the inflammatory origin of retinal detachment is strengthened by the exudative character of the retroretinal fluid. The chemical analysis of this fluid can give clues as to the functional integrity of the detached retina and can, therefore, be of prognostic value.

Max Hirschfelder.

O'Donoghue, W. D. Retinal vascular sclerosis. *Irish Jour. of Med. Science*, 1945, July, p. 214.

The author describes the ophthalmoscopic picture of retinal vessels in many diseases. True retinopathy begins when necrosis first occurs in the smallest terminal branches of the arterial tree. Then similar changes in the arterioles of vital organs have already passed their acme. Once these retinopathic changes are seen, the patient rarely lives more than two years.

Francis M. Crage.

Pischel, D. K. Diathermy operation for retinal detachment: comparative results of different types of electrodes. *Trans. Amer. Ophth. Soc.*, 1944, v. 42, pp. 543-567.

The author has attempted to determine and demonstrate the most efficient type of electrode for the surgery of detached retina. He briefly reviews the methods used since Gonin described his procedure in 1919. Experimental work is presented and 20 excellent photomicrographs demonstrate the difference in the retinal, choroidal, and scleral changes which result from the use of the large electrodes of Weve and Lindner and of the author's fine penetrating and perforating electrodes. Ignipuncture causes the scleral canal to become filled with a plug composed of episcleral tissue. For this reason ignipuncture is superior to surface coagulation. It gives a maximum choroidal and retinal reaction with a minimal scleral necrosis.

Carl D. F. Jensen.

Rønne, Henning. The ontogenesis of the course of the macular fibers. *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 199-201.

Rønne rejects the theories of Vossius and Ida Mann on this subject and attributes the structure of the paramacular fibers and the median raphe to a

passive centrifugal displacement of the nerve-fiber layer by the development of the fovea, which occurs considerably later. Action of a centrifugal movement in the inner layers of the retina is indicated also by the oblique course of the fibers in Henle's layer and in the transitory layer of Chievitz. Support for this theory is found also in the diminishing distance between the macula and optic papilla in the latest months of fetal life. Since the external nerve-fiber layer develops long before the fovea, it can be assumed that the growth of the macula forces the nerve fibers into a curved course, and in doing so they mechanically draw the macula towards the papilla. The radial course of the nerve fibers beyond the macula and in the nasal portion of the retina is their primary course, which, in the paramacular region, is altered by the development of the fovea. The arrangement of the fiber layer in a logarithmic spiral with the radius of curvature almost proportional to the foveal distance could result from a centrifugal force originating in the fovea. OPTIC NERVE AND TOXIC AMBLYOPIAS

Jensen, V. A. **A persistent Bergmeister papilla.** Acta Ophth., 1941, v. 19, pts. 3-4, pp. 267-271.

A case of this unusual congenital anomaly is reported. The papilla of the right eye was concealed under a bluish-white, shining, smooth, sharply outlined mass of tissue, from which fine offshoots extended peripherally to become inserted into a greyish-red, horse-shoe-shaped, circumpapillary retinal ridge which opened nasally and upward. The inner surface of the ridge ascended sharply, whereas the outer surface descended gradually toward the remainder of the eyeground. The macular and foveal reflexes were absent. The blood vessels were probably cilioretinal, since there were no traces of the hyaloid artery. This anomaly is explained by an arrest in the absorption of the Bergmeister papilla; the remaining prepapillary neuroglial tissue interferes with the development of the retina and is pulled forward as a circumpapillary ridge. (1 drawing, references.) Ray K. Daily.

13

EYEBALL AND ORBIT

Caillaud, M., and Fournie, F. **A case of tuberculous gumma of the eye.** Ann. d'Ocul., 1941, v. 172, no. 10, pp. 379-384.

A woman, 24 years of age, developed a painful swelling in the left lower temporal part of the sclera of the left eye. There was a swelling four d.d. in diameter in the temporal part of the fundus. She had had grippe followed by hemoptysis and pleurisy. The eye recovered in four months with only slight scarring. Chas. A. Bahn.

Serpa, José. Duane syndrome. *Rev. Brasileira de Oft.*, 1945, v. 4, Sept., pp. 43-45.

The symptoms presented, in a white Brazilian aged 20 years, were left enophthalmos, diminution of the palpebral fissure, slight internal strabismus, and torticollis. W. H. Crisp.

Zonder, H., and Ticho, A. So-called thyrotropic exophthalmos. *Brit. Med. Jour.*, 1945, June 16, p. 836.

Until a few years ago exophthalmos was thought to occur with Graves's disease only. Clinical and experimental studies have shown that aside from the thyrotoxic form there must be another, attributable to the thyrotropic factor of the anterior pituitary lobe. This form is named thyrotropic exophthalmos. The latter affects males predominantly and is rather uncommon. The exophthalmos is brought about by changes in the ocular muscles. In the thyrotoxic form there are three possible factors; namely, sympathetic stimulation of Mueller's muscle, adynamia of the rectus muscles, and anatomic changes in the muscle fibers, such as wasting, loss of striation, and fibrillation. In the thyrotropic form the proptosis is brought about by a muscle disorder that is characterized by diffuse extensive fibrosis, edema, marked round-cell infiltration, and a special type of fibrotic-muscle change, with disintegration and absorption. In the thyrotropic type there is greater proptosis as well as epiphora, photophobia, diplopia, and convergence difficulty, whereas in the thyrotoxic type patients are free from these symptoms, except in malignant thyrotoxicosis.

Three cases of thyrotropic exophthalmos are presented. In two there were marked decalcification of the

skull and sellar enlargement. Diabetic glucose-tolerance tests were made, and all patients responded favorably to diiodotyrosine. Two patients were given pituitary irradiation.

EYELIDS AND LACRIMAL APPARATUS

Amendola, Francisco. The lacrimal gland in ocular leprosy. *Rev. Brasileira de Leprologia*, v. 13, no. 1 (in *Arquivos Brasileiros de Oft.*, 1945, v. 8, June, p. 93.)

The author found that extirpation of the lacrimal gland produced a considerable improvement in the ocular condition of patients with leprosy. He concludes that the lacrimal gland is a focus of infection in ocular leprosy.

W. H. Crisp.

Broendstrup, Poul. Lateral dislocation of the medial canthus. *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 281-285.

A case of this rare congenital and inherited deformity is reported. The eyes of this five-year-old girl were normal in other respects. The inner canthi were misplaced laterally, covering the caruncle and shortening the palpebral fissure horizontally. Medially the sclera was invisible, the nasal edge of the cornea was covered, and at the inner angle the lids came together without forming the lacrimal lake. The lacrimal puncta were placed more temporally than is usually seen. The caruncle, hidden behind the lids, was flat and small and closer to the lower lid than normal. The eyebrows were longer than usual, and the fine hair on the cheeks and forehead were very prominent. The pathogenesis of this anomaly has not been determined. Van der

Hoeve attributes it to an excessively long anlage for the lacrimal canal; the caruncle becomes too large and exerts an irritating effect on the inner commissure, which reacts by growing laterally and covering the caruncle. Waardenburg considers the deformity an arrested stage in the embryonic development that is reached in the third month of fetal life. (photograph, references.) Ray K. Daily.

Filatov, V. The tubular stem in ophthalmology (translation by D. V. Giri). Indian Jour. Ophth., 1945, v. 6, July, pp. 23-31; and Oct., pp. 43-50.

This is an English translation, in an Indian journal, of a paper by the Russian Filatov, but without indication of its previous journal origin. It deals with many varieties of skin flap used in plastic surgery. W. H. Crisp.

Muskatblit, E., and Targen, N. A. Ringworm of the eyebrow. Arch. Dermat. and Syph., 1945, v. 52, Aug., p. 116.

Ringworm of the eyebrow is rare. The case reported demonstrates the importance of examination by means of filtered ultraviolet rays, which show infection of hairs by *Microsporon* when ordinary light fails to reveal any lesion of the hairs or skin.

It is also suggested that during examination for ringworm the Wood light be directed not only toward the patient's scalp but toward the face. If this is done systematically, it is possible that ringworm of the eyebrows will be found to be more common than is supposed. Theodore M. Shapira.

Rapin, M. Restoration of the upper and lower lid. Ophthalmologica, 1943, v. 105, May, pp. 233-239.

After discussing the standard meth-

ods of plastic repair of the upper and lower lid, the author describes his own method which he used to repair extensive damage caused by lupus vulgaris. He restores the upper lid in two stages. First he lines a flap from the skin of the forehead with mucous membrane. In the second stage he grafts the flap into the proper position.

Max Hirschfelder.

Thiel, R. Reconstructive surgery of the lacrimal passages. Klin. M. f. Augenh., 1942, v. 108, Sept.-Oct., p. 576.

Thiel describes a method for the surgical reconstruction of the lacrimal canal which has lost its patency. His method is essentially a modification of the procedure of Nižetić. In place of the wax mandrel Thiel uses a conical style molded of elastic polyviol. He forms a new duct by covering the style with mucous membrane from the lip. The grafted mucous membrane that envelops the style is fixed around it with sutures before it is inserted in the wound bed. This tubule is sutured into the opening in the tear sac as well as to the conjunctiva. The style is left in position for eight days. It is advisable to fill the new-formed canaliculus with oil or an ointment every other day after the removal of the style. Only the lower duct is restored. (11 illustrations.) F. Nelson.

TUMORS

Biró, I. A case of metastatic orbital carcinoma with enophthalmos. Acta. Ophth., 1941, v. 19, pts. 3-4, pp. 255-260.

Biró reports an unusual case of metastatic orbital carcinoma in which there was an initial 3-mm. enophthalmos. The woman, 41 years of age, had both breasts removed within a year be-

cause of malignant tumors. She complained of diplopia and ptosis of the right upper lid of two weeks' duration. There was restriction of motion up and out and a feeling of resistance in the orbit. She was given X-ray therapy without success. (Photographs, references.)
Ray K. Daily.

Buerki, E. Retothel sarcoma of the orbit. *Ophthalmologica*, 1943, v. 105, May, pp. 253-267.

Retothel sarcoma is a neoplasm which is almost unknown in ophthalmologic literature. The tumor is also known as Ewing's sarcoma. Though there is still some question about its cytogenesis, it is probable that it is reticuloendothelial in origin.

The clinical and pathologic manifestations in a case of generalized retothel sarcomatosis, which at first appeared as an orbital tumor, are described. The author cites the four known cases of retothel sarcoma in the ophthalmic literature and believes that many of the round-cell sarcomas of the orbit previously described may be retothel sarcoma. Lymphosarcomas which arise from lymphoblasts and lymphocytes have to be distinguished from retothel sarcoma. (References.)

Max Hirschfelder.

Pascheff, C. Investigations of hemoblastic growths in the orbit and local eosinophilia in chloroma. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., p. 529.

Of the diseases of the hemopoietic organs which Sternberg names hemoblastoses, lymphoma, myeloma, and chloromata occur in the orbit. Lymphoma belongs to the group of primary aleukemic hyperblastic processes of the lymphatic system. Pascheff reports two cases, one in a man of 70 years and one in a boy of three. The

diagnosis was verified by puncture biopsy. X-ray treatment cured both completely. Myeloma in the orbit is very rare. It is a malignant tumor unaccompanied by hematologic changes. Two cases of orbital chloroma were found among 500,000 patients seen during a period of 42 years. Chloroma develops in the periosteum, usually in the upper rim, causing a typical exophthalmos. Its presence is noted in one orbit, but eventually both sides are involved. Of diagnostic importance is a leukemic or subleukemic blood picture, with large undifferentiated cells that are also found in the tumor itself. The green color of the tumor is not always manifest. It usually occurs in young children between the second and seventh year of life. Radium treatment is of no avail. Of Pascheff's patients, one died three weeks and one three months after admission. Postmortem examination of one of these revealed metastases in the lymph nodes of the neck, thorax, and abdomen. All abdominal lymphatic organs as well as the liver and the kidneys, the cranial bones, and ribs were invaded by the tumor. In the other patient, the tumor was found in both orbits, in the occipital bone, one rib, all vertebrae, and in dura of the cerebellum. There was anemia of all the organs and parenchymatous degeneration of the myocardium, liver, and kidneys. The bone marrow was reddish green. There were eosinophilic myelocytes in the tumor. (10 photographs, references.)

F. Nelson.

Paulo, A., Jr. Primary malignant melanoma of the optic disc. *Rev. Brasileira de Oft.*, 1945, v. 4, Sept., pp. 29-41.

The patient was a married white woman aged 50 years. For three years

the vision of the right eye had been progressively cloudy. The papillary origin of the tumor was indicated by the fact that the papillary portion of the tumor was much more considerably developed than the choroidal expansion, and that the connective-tissue network of the lamina cribrosa was displaced forward. The tumor was highly pigmented. (7 illustrations, references.)

W. H. Crisp.

Szabo, G., and Cseh, E. *Neurinoma of the sclera near the limbus*. *Ophthalmologica*, 1943, v. 106, July, pp. 14-25.

The authors describe a tumor as large as a hazelnut in the upper outer quadrant of the right eye of a boy 12 years of age. Histologic examination showed a typical neurinoma. The tumor was adherent to the sclera, but not to the conjunctiva. These tumors are rare and develop from nerve loops situated near the limbus. No other similar tumors, such as neurofibromas or warts, were found in the patient. The authors review the literature concerning neurinomas in different parts of the eye. (Bibliography.)

16

INJURIES

Anderson, O. C. *Traumatic blood cyst of the orbit*. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., p. 547.

A case of orbital blood cyst is reported. The patient, a man aged 44 years, had been hit by a hammer in the region of the left eyebrow. A short wound was sutured but during the next three days a large swelling necessitated the removal of the stitches. While this was being done, a small purulent hematoma escaped from the wound. Two years later the first symp-

toms of tumor formation in the orbit were observed. X-ray studies revealed cloudiness in the upper half of the orbit. Because a retrobulbar tumor was suspected, a surgical operation was suggested but denied by the patient. Two years later the exophthalmos had increased, and the vision of the left eye was now 5/15. Numerous horizontal retinal folds were visible at the posterior pole. Orbitotomy revealed an ochre-yellow, brittle substance and remnants of brownish red blood in a cystic sac. The orbital periosteum was destroyed in some places, and the pressure of the cyst had produced a small depression in the bone behind the upper orbital rim. Surgery is the only possible treatment, but total removal of the wall of the cyst is probably not imperative because the structure consists of connective tissue and is not lined by epithelial cells. F. Nelson.

Carvalho Pinto, W., and Mendonça de Barros, J. *Intraocular foreign body and bulbar siderosis*. *Arquivos Brasileiros de Oft.*, 1945, v. 8, June, pp. 71-74.

A stoneworker, aged 42 years, had a completely opaque left crystalline lens, with a slightly greenish tint and small deposits of a rusty color on the anterior capsule. The pupil was partially dilated. Most of the corneal parenchyma showed pigmentation. The outlines of the iris were blurred, the stroma was slightly atrophic, and some areas were depigmented.

Pain being elicited by the approach of an electromagnet to the eye, an incision was made in the sclera, and the magnet promptly withdrew a dark metallic fragment measuring 2.5 by 0.5 mm. The patient subsequently recalled that about a year and a half earlier, in striking a chisel with a mallet, the left eye had been hit by a

fragment, the blow causing him temporarily to lose his senses. (1 color plate.) W. H. Crisp.

Kjerrumgaard, Erling. A case of ocular chalcosis. *Acta Ophth.*, 1941, v. 19, pts. 3-4, pp. 261-266.

A boy, 14 years of age was hurt by the explosion of a cartridge, as a result of which numerous particles of copper from the cartridge case penetrated both orbits and the right eyeball. Subsequently both eyes developed sunflower cataracts, and the fragment of copper in the right eye became visible as a dark body in the fundus, covered with organized tissue. The point to be stressed is the relatively good prognosis of chalcosis. In this case vision in the two eyes was 6/6 and 6/9, four years after the injury. (2 color photographs, references.) Ray K. Daily.

Krimsky, Emanuel. Extensive knife wound of the orbit with complete recovery. *The Eye, Ear, Nose and Throat Monthly*, 1943, v. 22, Feb., pp. 58-60.

A Negro, 37 years old, was wounded in the head by a butcher knife. There was proptosis of left eyeball with profuse hemorrhage from the wound, and the point of the knife could be seen on the posterior pharyngeal wall. X-ray studies revealed the presence of the blade of the knife, which was 9 inches long and about 3½ inches wide. It had entered near the outer wall of the left orbit and extended almost vertically downward for about 5 inches. The blade, which was firmly imbedded in the skull, was removed, and the patient made an uneventful recovery. The vision was normal, and the muscle functions not disturbed. (2 figures.)

Melchiore Lombardo.

Lieux and Saint-Martin, R. Injury of the trigeminal nerve by retroöbital

shell splinter. *Ophthalmologica*, 1943, v. 105, Jan., pp. 1-12.

In a patient who had been injured by a large shell splinter which had penetrated the orbit to the Gasserian ganglion, the ophthalmic nerve, the upper branch of the maxillary nerve, and the cheekbone were severed. Complete paralysis in the field of these two nerves and loss of the deep sensitivity were noted. However, there was no neuromyolytic keratitis nor any alteration of the retinal arterial pressure nor of the ocular tension. (Bibliography.)

Max Hirschfelder.

McGrigor, D. B., and Samuel, E. War wounds of the orbit and eyeball. *Brit. Jour. Radiology*, 1945, v. 18, Sept., p. 284.

A short review of methods of the radiology of intraocular foreign bodies is presented as part of a symposium on radiology of war injuries. Only 50 percent of intraocular foreign bodies were demonstrable by radiographic examination. The Sweet method of localization and an anterior-posterior projection method were preferred. Observations on the more frequent fractures of the orbital wall are discussed.

Morris Kaplan.

Ostow, M. The frequency of blinking in mental illness. *Jour. Nervous and Mental Dis.*, 1945, v. 102, Sept., p. 294.

Blinking recurs at a centrally regulated rate, which is fairly constant in the individual. In this respect it resembles the respiratory rhythm, although it is not so regular. Blinking increases in states of excitement, increased attention, surprise, cogitation, drowsiness and yawning, and in the prehypnotic state. Increased movement of the eyeball, concentrated study, and

interest in objects decrease the rate of blinking.

Patients, with functional mental disease blinked less uniformly and more rapidly than normal individuals and those who have recovered from a recent functional disturbance of the nervous system. The rate of blinking does not vary in a regular relationship with other subjective or objective manifestations of nervous disease. Its frequency seems to vary directly with the individual's interest in his environment and inversely with the clarity of his comprehension of it.

The authors tentatively assume that the center of blinking is in the pallidohypothalamic tract.

Francis M. Crage.

Saint-Martin, R. *Bitemporal hemianopsia due to injury*. *Ophthalmologica*, 1943, v. 105, June, pp. 289-298.

A fracture of the left frontal bone was followed by bitemporal hemianopsia. There was total optic atrophy in the right eye, and atrophy of the nasal side of the optic nerve in the left eye. The sense of smell was lost. The author assumes that the hemianopsia is due either to a tear in the chiasm or to microscopic rents in the midportion of this structure. Max Hirschfelder.

Velhagen. *Rare histologic findings in an eye injured by wood*. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., p. 553.

The left eye of a man, aged 74 years, had been injured by a wooden splinter which the patient had removed with his fingers. Six months later the eye had to be enucleated because of danger of sympathetic ophthalmia. Histologic examination revealed chronic uveitis, traumatic cataract, hyalitis, anterior synechia, and an oval structure at the site of the corneal perforation. The

cells composing this structure were hexagonal. Some of them contained minute granules; some, indistinctly stained clouds; and others, nuclei varying in number and shape. Some were round, some elongated, and some were horseshoe shaped; all were distinctly stained with hematoxylin. The cell membranes were doubly refracting. The whole formation was encapsulated in a membrane containing giant cells with pigment granules, epithelioid cells, and round cells. Two botanists affirmed that the structure was composed of plant cells but that the nuclei found in the inner cells were not derived from plants. They were either the nuclei of human giant cells or of leucocytes. Small vegetable foreign bodies can be partly or completely absorbed by human cells, not only in the orbit but also in the interior of the globe. (1 microscopic drawing, 1 photomicrograph, references.) F. Nelson.

Wiser, H. J. *Eye injuries in war casualties aboard a hospital ship*. *United States Naval Med. Bull.*, 1946, v. 46, Jan., p. 67.

Ocular injuries were present in 8 percent of all casualties brought aboard. Treatment, though at times extensive, was actually an interim treatment before final removal to a fixed hospital. Severe lacerations and multiple foreign bodies were present in most of the eyes. The gratifying results are ascribed to the very generous use of penicillin which was given by injection, in ointment, and by instillation. It was also used for irrigation in solutions which contained 2,000 units per cubic centimeter. Morris Kaplan.

gland in ocular leprosy. *Rev. Brasileira de Leprologia*, v. 13, no. 1 (in *Arquivos Brasileiros de Oft.* 1945, v. 8, June, p. 93.) (See Section 14, Eyelids and lacrimal apparatus.)

Bischler, Vera. **Malformations of the eye and of the heart.** *Ophthalmologica*, 1943, v. 106, Oct., pp. 169-181.

The author found reports of only 14 cases of coincidental malformation of the eye and the heart, and adds four observations of her own. In two patients there was a coloboma of the uveal tract, and in two the lens was abnormal. Three of the patients had so-called Roger's heart disease, the fourth had a probable perforation of the cardiac septum. (Bibliography.)

Max Hirschfelder.

Clark, C. P. **Albinism with co-existing anomalies of the central nervous system.** *Trans. Amer. Ophth. Soc.*, 1944, v. 42, pp. 250-261.

Clark presents an interesting review of albinism. Pigment in animal tissue results from the union of a chromogen and an enzyme which activates the chromogen. Where either of these is absent there is no pigment. Lack of pigment in tissue is known as albinism and is a hereditary genetic defect. Waardenburg recognizes seven types of albinism on the basis of the degree of pigment paucity, the tissues which are involved, and the pattern according to which the defect is inherited. Clark describes seven patients. The first patient exemplified a case of total universal albinism (Waardenburg's Type 1), the others incomplete universal albinism (Type 2). (2 figures, bibliography.)

Dame, L. R. **Eye and ear sequelae of scrub typhus fever.** *Bull. U. S. Army*

Med. Department, 1945, v. 4, Nov., p. 554.

One half of fifty patients who were convalescing from scrub typhus fever had some transient ocular and aural symptoms. No diminution of vision nor of hearing was found, however there were moderate enlargement of the blind spot and contraction of visual fields in most of the patients, and occasionally a scotoma was found. Moderate derangement of the vestibular system after caloric stimulation occurred.

Morris Kaplan.

Frandsen, H., and Lundh, B. **Riboflavin and arboflavinosis with special reference to eye changes.** *Acta Ophth.* 1941, v. 19, pts. 3-4, pp. 331-345.

A brief review of the literature is followed by a detailed report of the author's own studies of 104 patients with an average age of 75 years. Seventy-five patients had symptoms of ariboflavinosis, which consisted of superficial vascularizing keratitis, cheilitis, abnormal redness of the moist prolabium, redness and atrophy of the mucous membrane of the tongue, stomatitis, dysphagia, skin changes on the face and extremities, and nail changes. Ocular symptoms were found in 48 of the 75 patients; the subjective symptoms were photophobia, fogged vision, smarting and itching of the eyes, asthenopia, and dull vision. The objective symptoms were conjunctivitis with conjunctival and slight ciliary injection, and vascular development in the limbus, and arcus senilis as far as 3 mm. into the cornea. The intramuscular administration of 5-10 mg. of riboflavin daily affected a cure in 70 percent of 47 patients treated; the average treatment period was 24 days, and the total riboflavin intake was 216 mg. Three of 13 patients with no evidence

of riboflavin deficiency, treated for several months with large quantities of nicotinic acid, developed photophobia and corneal vascularization. These changes promptly disappeared under riboflavin treatment. There is a close connection between the effect of riboflavin and nicotinic acid; in people with low vitamin-B reserve, symptoms of ariboflavinosis may be produced by intensive nicotinic-acid therapy. The best therapeutic results were derived from intramuscular administration. (Bibliography.) Ray K. Daily.

Rodriguez, B., Rodriguez Barrios, R., and Oreggia, A. A new type of peduncular syndrome. Internuclear ophthalmoplegia and bilateral cerebellar syndrome from a tegmental lesion. Arch. Uruguayos de Med., etc., 1945, v. 27, Oct., pp. 353-370.

The authors' patient, a woman of 62 years, had a vascular syndrome of the mesencephalon. The softening occurred in the peduncular tegmentum. The clinical picture, of sudden onset, included paralysis of associated ocular movements (internuclear anterior ophthalmoplegia) and a bilateral cerebellar syndrome. An initial hemiplegia rapidly recovered. Various signs disclosed involvement of the posterior longitudinal bundle. The authors regard the case as representing a new mesencephalic syndrome which they propose to name "oculocerebellar syndrome from tegmental lesion." (11 figures, references.) W. H. Crisp.

HYGIENE, SOCIOLOGY, EDUCATION,
AND HISTORY

Charlin Correa, Carlos. Arch. Chilenos de Oft., 1945, v. 2, Sept.-Oct.

This 53-page issue is entirely devoted to addresses and memorials de-

livered on the occasion of the funeral of this dean of Chilean ophthalmologists. Carlos Charlin Correa was born in Santiago de Chili in April, 1885. He studied in France, Switzerland, and Italy, published in 1924 a treatise on clinical ophthalmology, and was particularly known for his description of the syndrome of the nasal nerve which has been a good deal associated with his name. (Bibliography, portrait.)

Farias, Natalicio de. Prevention of blindness. Arquivos Brasileiros de Oft., 1945, v. 8, April, pp. 41-46; also Rev. Brasileira de Oft., 1945, v. 4, Sept., pp. 47-53.

This is a report presented to the second Pan-American Congress of Ophthalmology, Montevideo, November, 1945, under the following headings: organization for the prevention of blindness, official and governmental (National League for the Prevention of Blindness and Santa Luzia Foundation); and suggestions presented by the author to the Congress. The author suggests that the struggle against blindness needs to be more individual than governmental in character, responsibility resting largely upon physicians, dentists, pharmacists, opticians, nurses, and midwives. He desires to see published in the United States of America a review in Portuguese, Spanish, and English, on the progress of ophthalmology and related subjects, and to be distributed gratuitously.

W. H. Crisp.

Farmer, E. Occupational adjustment of the blind. The Lancet, 1945, Oct. 13, p. 474.

The author, an industrial psychologist, divides the blind into three groups: those who are blinded since

infancy and have no visual memories; those blinded by illness; those blinded by trauma. Most persons in the last group are civilian or military war casualties. He insists that the blind have only their blindness in common and differ in other respects like all people. Intelligence tests are being devised which will be entirely unlike those used for normal individuals. These should determine the capacity of the individual to adapt himself to his blindness and to a vocation. It is shown that the commonly held belief that the nonvisual senses are better developed among the blind than among the sighted is erroneous. Touch, for instance, is often inferior among the blind because the skin of the finger tips is thickened from constant use. More care should be given to developing vocational tests for the blind because it takes longer to prepare for a vocation, and disappointment in case of failure is apt to be greater.

Morris Kaplan.

Garden, R. R. *Child health*: 15. *The blind child*. *The Practitioner*, 1945, v. 155, Sept., p. 180.

In England between the years 1919 to 1943 the number of people who are blind from infancy was reduced by one half. This is ascribed largely to the control of gonorrheal ophthalmia. The first system of education for the blind occurred in France in 1784, and was followed in England in 1791. The au-

thor insists that blind children under the school age of five years should be kept at home for normal infant training and with strict avoidance of overprotection and pampering. When they are five years old these children should be placed in schools for the blind, which is compulsory in England. Elementary and secondary education should differ little from the education for the sighted. Morris Kaplan.

Gradle, H. S. *The development of an ophthalmologist*. *Ophth. Ibero Amer.*, 1945, v. 7, no. 2, pp. 95-100 (in Spanish), and pp. 100-105 (in English).

The author briefly outlines an adequate course of study for the profession of ophthalmology, giving the number of hours he considers should be assigned to each of 16 sections of the subject during a preliminary course of study, and in another tabulation an outline of the clinical division of the student's training. W. H. Crisp.

Queiroga, G. *Teaching of ophthalmology in the United States*. *Arquivos Brasileiros de Oft.*, 1945, v. 8, June, pp. 75-85.

The author recounts his experiences as an auxiliary resident in the Eye Clinic of the University of Iowa from October, 1943, to December, 1944. He inserts a number of details drawn from the University catalogue.

Edited by DR. DONALD J. LYLE
904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month

DEATHS

Dr. Sullivan L. Andrews, Lewiston, Maine, died November 26, 1945, aged 68 years.

Dr. Robert H. Butler, Bellefontaine, Ohio, died November 21, 1945, aged 64 years.

Dr. Walter S. Franklin, Santa Barbara, California, died January 2, 1946, aged 67 years.

Dr. James P. Goray, Fitchburg, Massachusetts, died November 12, 1945, aged 78 years.

Dr. John R. Harrison, Greer, South Carolina, died November 22, 1945, aged 53 years.

Dr. Spencer S. Howe, Bellingham, Washington, died November 8, 1945, aged 69 years.

Dr. John L. Keane, Dubuque, Iowa, died November 3, 1945, aged 49 years.

Dr. Charles S. Marsden, San Diego, California, died October 13, 1945, aged 72 years.

Dr. George A. Moore, Palmer, Massachusetts, died October 6, 1945, aged 74 years.

Dr. Edgar L. Morrill, Fort Collins, Colorado, died January 19, 1946, aged 69 years.

Mr. Max Poser, Rochester, New York, died January 4, 1946, aged 75 years.

MISCELLANEOUS

The Annual Congress of the Ophthalmological Society of Egypt took place at the Memorial Laboratory, Giza, Egypt, on March 15-16, 1946. The symposium of the Congress was on "Tuberculous manifestations in the eye."

A tri-session conference of civilian doctors and Army Medical Corps officers, specializing in ophthalmology and related plastic surgery, was held recently at Valley Forge General Hospital, Phoenixville, Pennsylvania.

Lt. Col. Elliott Randolph (MC), Chief Consultant in Ophthalmology to the Surgeon General, and Dr. James N. Greear, Jr., former Chief of the Valley Forge General Hospital Eye, Ear, Nose, and Throat Section, were among the guests present at the meeting.

A total of 70 ophthalmologic cases were examined and discussed during the conference, which was opened with a discussion on "Military plastic surgery," by Lt. Col. Bradford Cannon (MC), Chief of the Valley Forge General Hospital Plastic Surgery Section. Lt. Col. Phillips Thygeson (MC), Chief of the Eye, Ear, Nose, and Throat Section, presided.

The following civilian ophthalmologists were among those attending: Drs. P. Robb McDonald, Alan Crandall, Francis H. Adler, Walter I. Lillie, Irving H. Leopold, Harold Scheie, and Joseph Waldman.

The book publishing firm of W. W. Norton and Company announce that they are again inviting manuscripts for submission to be considered for the Norton Medical Award of \$3,500.00 offered to encourage the writing of books on medicine and the medical profession for the layman. Closing date for submission of manuscripts this year is November 1, 1946. All particulars relating to requirements and terms may be had by addressing W. W. Norton and Company, Inc., 70 Fifth Avenue, New York 11, New York.

SOCIETIES

At the meeting of the Milwaukee Ophthalmic Society, held on February 26th, the following program was presented: "Ocular leprosy" by Dr. George Dunker; "The stability of penicillin in ophthalmic solutions" by Dr. E. Grossman; "Problems of facial reconstruction" by Dr. B. P. Churchill; and "The fundus of scrub-typhus" by Dr. John Hitz.

A combined meeting of the Philadelphia Roentgen Ray Society and the Section on Ophthalmology of the College of Physicians of Philadelphia was held on January 17, 1946. Dr. Carlos Santos, professor of radiology, Lisbon, presented a paper on "Physiologic and technical fundamentals of stereoscopic fluoroscopy especially adapted for the removal of foreign bodies."

The Brooklyn Ophthalmological Society held its regular meeting on February 21st. A demonstration of the Berman metal locator was made by Samuel Berman. Dr. Walter V. Moore, Col. (MC), spoke on "At home and overseas." Dr. Mortimer Lasky presented a paper on "Eye pathology from the Bulge and Siegfried Line."

At the meeting of the Buffalo Ophthalmologic Club, which was held on February 14th, Dr. John H. Dunnington presented a paper on "The present status of penicillin in ophthalmology." Following this an informal round-table discussion on "Ocular surgical problems" was held.

At the second clinical conference of the Chicago Medical Society, held from March 5th to 8th, Dr. Peter C. Kronfeld spoke on "Eye conditions that should be recognized by general practitioners."

The Reading Eye, Ear, Nose, and Throat Society of Reading, Pennsylvania, held its fifty-first meeting on January 16, 1946, at the University of Pennsylvania. Dr. Francis Heed Adler conducted the program for the Eye Section, which included the following papers: "Chemotherapy in ophthalmology" by Dr. Irving H. Leopold, "Penetrating wounds" by Dr. Shay, and "Artificial tears" by Dr. Lamott.

PERSONALS

Dr. William B. Clark, professor of ophthal-

mology, Tulane University, Louisiana School of Medicine, has just returned to New Orleans from a three weeks' visit to Guatemala and Mexico, where he is continuing his research project on the ocular manifestations of onchocerciasis.

Dr. Claude S. Perry, Columbus, has been named acting chairman of the department of ophthalmology, Ohio State University College of Medicine, Columbus, Ohio, with the rank of associate professor.

BOWEN'S DISEASE OF THE CONJUNCTIVA*

V. R. KHANOLKAR, M.D.

Bombay, India

Bowen¹ in 1912 described a chronic condition of the skin which he had observed in two patients and which was characterized by certain clinical and histologic features. The lesions appear as single or multiple papulo-squamous nodules in the skin that are sharply circumscribed from the surrounding area. They may be pale or dark red in color. The nodules are firm, slightly raised above the skin, and smooth or papillomatous on the surface. Two years later Darier² reported four further cases, in which he confirmed the findings of Bowen, and minutely described the microscopic structure of the cells that showed the abnormal features. Since then, many cases have been reported from observers in different parts of Europe and America which have essentially supported the earlier observations and have substantiated the opinion of Bowen that the initial lesion, if not completely eradicated exhibits a decided tendency to an eventually malignant transformation. The clinical form of the disease of the skin is extremely variable and may appear as simple erythematous spots (initial stage of Darier), as papules, or as crusty, hyperkeratotic, vegetating plaques. The microscopic characters, however, are remarkably constant. It has therefore been suggested—I believe wrongly—that the disease entity, if it exists at all, is more in the nature of a

histologic pattern than a definite clinical condition. Similar histologic changes have been described in localized patches on the mucous membranes, particularly the vulva (Richon³), glans penis (Jessner⁴), and the tongue. Recent reviews by Stout⁵ and by Cipollaro and Foster⁶ have fully described the known facts regarding the location and malignant manifestations of the disease.

The following case is described because the original lesion and the repeated recurrences presented all the histologic characters of Bowen's disease in the epithelium covering the sclerotic of the eyes. It was probably the first case of the disease reported⁷ in that location, and it had been observed for more than eight years until the death of the patient from some other cause. Recently McGavic⁸ has reported five specimens from the Eye Institute, New York, which he believed showed the histopathologic changes of Bowen's disease occurring in the cornea and conjunctiva. McGavic has stated that "the clinical course of the lesions is so unusual, the microscopic picture so characteristic, and the problem of therapy so challenging that a discussion of the subject is in order." I had hesitated to report the case fully as my opinion regarding the nature of the lesion was at variance with that of an eminent English ophthalmologist, and the patient was under observation until recently.

* From Tata Memorial Hospital.

Fig. 1 (Khanolkar). Photomicrograph of a section of the entire tissue removed on January 11, 1938, showing a sharp transition from the normal epithelium at the periphery to the thickened altered conjunctival epithelium in the neoplastic zone. The epithelial cells are disposed in a disorderly manner, and there is a tendency to folding of the thickened epithelium. The epithelial cells are clearly demarcated from the subepithelial tissue, which shows increased vascularity and a mild inflammatory reaction.

Fig. 2 (Khanolkar). A photomicrograph of the tumor area in figure 1, showing a proliferation of the epithelial cells, a loss of the neat palisade arrangement of cells in the basal layer, and a marked variation in the size and shape of squamous cells (poikilokarynosis). A few giant cells and cells with multiple clumped nuclei are also seen. Two very large cells with a bizarre arrangement of chromatin are present.

Fig. 3 (Khanolkar). Photomicrograph of the central portion of the tissue excised on May 11, 1938. The epithelium is thrown into well-marked folds and papillary processes. The histologic characteristics of the tumor cells remains similar to those in the original lesion.

Fig. 4 (Khanolkar). Photomicrograph of a small area from one of the papillae in figure 3.

CASE REPORT

A physician, aged 70 years, noticed an acute inflammation of the conjunctiva of his right eye for the first time in January, 1936. He had lost his left eye as a small boy following an injury on the cricket field, and he attributed the conjunctivitis to an undue strain on the eye during the course of his work. The inflammation subsided after a couple of days of treatment with drops of 10-percent argyrol solution. The conjunctivitis began to recur every three to four months, but cleared up every time after a short course of argyrol instillations. In July, 1937, a fresh attack of conjunctivitis did not clear up completely with the usual treatment, but left an injected patch half way between the limbus and the outer angle of the eye, with two or three dilated blood vessels coursing across it. The presence of the patch was attended by no pain, although it led to a feeling of discomfort, yielding a sensation of a foreign body on the eyeball. Treatment with the usual medicaments led to no improvement of the condition. Three months later (October, 1937) the patch appeared to be slightly raised above the surface, reddish in color, and irregular in outline. A few weeks later the affected area began to spread rapidly and encroach on the limbus. The case was diagnosed as a papilloma of the conjunctiva by Dr. B. P. Banaji and he decided to excise the involved portion of the conjunctiva. At the operation (January, 1938) the conjunctiva of the affected area was removed by a superficial incision, and the underlying sclera was scraped. The nodule was not adherent to the deeper

structures (figs. 1, 2). The area that had been operated on healed completely without leaving any noticeable scar. The excised tissue was examined histologically and was reported upon by me as follows: "The conjunctival epithelium in the healthy portion, which is slightly thinned out, passes abruptly into

Fig. 6 (Khanolkar). Clinical appearance of the lesion as seen on the occasion of the third recurrence in April, 1939. The vascularity of the lesion is noticeable.

an epithelial lining several layers thick. In this affected area the epithelium is slightly folded with a small amount of keratinization in the most superficial layers. The normal arrangement of cells appears to be disturbed in the altered epithelium, and certain large cells are seen sprinkled or grouped between normal cells without any definite arrangement. These cells were about 8 to 10 times the size of normal polyhedral cells. Some of them showed the chromatin arranged in atypical mitotic figures lying in the middle of finely granular cytoplasm, whereas others were found

Fig. 5 (Khanolkar). A higher-power photomicrograph to show the microscopic features of the tumor cells. The "clumping cells" of Bowen and the "corps ronds" of Darier are easily recognizable.

Fig. 7 (Khanolkar). Photomicrograph of the nodule excised in April, 1939, showing a whorled arrangement of elongated spindle-shaped epithelial cells and their anaplastic character.

with several large nuclei clumped together in the center of monstrous cells. Some of the remaining cells, which were about normal in size, showed hyperchromatic dense nuclei surrounded by clear spaces (intracellular edema). Many darkly staining round clumps of chromatin are seen surrounded by clear zones ('corps ronds' of Darier). None of these cells is seen to be lying disassociated from its neighbors in clear spaces of intracellular edema. The fine clear lines separating the epithelial cells are clearly seen in most areas. A rapidly proliferative activity in the cells is evidenced by a large number of mitoses in the thickened epithelium. The subepithelial tissue consists of a richly vascular connective tissue with a mild inflammatory exudate mainly consisting of lymphocytes and histiocytes. *Diagnosis:* There is evidence of an atypical change in the cells of the squamous epithelium suggestive of a precancerous condition (Bowen's disease.)"

Three months later a small opaque nodule appeared near the site of the original lesion and was removed on May 11, 1938. A histologic examination of the excised piece showed that the affected epithelium was thrown into folds or papillary processes, but there was no evidence of infiltration of epithelial cells into subjacent connective tissue. The tumor cells presented a more advanced atypical change than those in the first piece, with evidences of a more noticeable variation in the size and shape of cells (figs. 3, 4, 5). The patient was naturally worried about the condition of his only existing eye and went to England for consultation and advice. He was seen by one of the leading ophthalmologists in that country in June, 1938, and the following opinion was given: "I have examined the slides which Dr. — has shown me and I am satisfied that the original growth, which was removed in January, is a simple papilloma

without any trace of malignancy. The recurrence which was excised in May is again a simple papilloma, but the slightly different character of some of the cells would lead me to suggest that if it recurs, which it probably will, it should again be excised widely and radium applied for some days after" (June 23, 1938).

There was another recurrence soon after the patient's return to India, in August, 1938, on the conjunctiva near the area which had been removed in October, 1938. The histologic characters of the excised nodules were again reported as being similar in structure to the original piece examined in January.

The patient remained well for the next five months (until March, 1939), when it was noticed that a small white nodule had appeared on the conjunctiva near the limbus. It did not appear to grow much during the first fortnight but took on an accelerated growth thereafter. It was noticed that the nodule had reached a diameter of 3 mm. in the next fortnight. It was raised above the surface, grayish white in appearance, and showed a fine network of dilated blood capillaries at its periphery. In its medial spread it had passed the limbus and was extending on to the cornea (fig. 6). The nodule was removed in April, 1939 (fig. 7), with a wide margin of conjunctiva beyond its outer limits.

The histologic features of the last piece deserve a detailed description. "A small nodule of thickened conjunctival epithelium is seen continuous with the adjacent epithelial lining. The tumor tissue is sharply demarcated from the underlying vascular connective tissue. The nodule is almost entirely composed of bundles or whorls of elongated spindle-shaped cells with few multinucleated cells scattered in the tissue. The spindle cells show all stages of transition from the polygonal

squamous epithelial cells. The chromatin in the nuclei of the tumor cells is dense and compact. The chromatin network and nucleoli are not clearly seen. There appears to be a marked variation in the size and shape of cells. *Diagnosis:* Spindle-cell carcinoma of the conjunctiva."

The patient went for further treatment to England in May, 1939, and was treated with two applications of radium. He could not receive the third application owing to the outbreak of hostilities in Europe and his desire to return to India immediately. Details of dosage and method of radium therapy employed in the case are not available. There was no recurrence of the eye lesion up to the time of the patient's death, 4½ years later.

DISCUSSION

The case presents many interesting features in as much as it was possible to observe the initial lesion and the three subsequent recurrences over a period of three years and to follow the course of the disease from the earliest subjective disturbances till the death of the patient 8½ years later. It was possible to study the histology of the tissue removed on

four different occasions, when it was observed that the structure manifested a progressive alteration from a relatively benign lesion to a definitely malignant tumor. The question of treatment in these cases has given rise to conflicting opinions. It may be suggested that an alert ophthalmologist should, in a suspected case, remove the whole superficially situated nodule by surgical excision and send the tissue for a careful histologic investigation. Treatment by irradiation may be immediately instituted if the lesion is reported to be Bowen's disease of the conjunctiva. The treatment of choice would be utilization of the unfiltered radiation from a bare radium bulb. The total dose would comprise about 500 millicurie-minutes, distributed over two to three applications at intervals of a fortnight.

SUMMARY

One more case of Bowen's disease of the eyeball has been described, which had been under observation for a period of 8½ years. The clinical and histologic findings have been described and the treatment of the disease has been discussed.

PREGLAUCOMA*

HARRY S. GRADLE, M.D.

Chicago

Ever since I first proposed the term "preglaucoma," in 1924, to designate the condition in which an ocular hypertension may be expected to develop in the course of time (one year previously Koeppe had used the term "preglaucomatous stage" in referring to the pigment disturbance he described), much work has been done and much has been written about tests to confirm such diagnosis. But nothing has been said about the type of hypertension that can be anticipated from the character of the preglaucomatous eye, and it seems to me of importance that such definite differentiation be established. Not only will the type of preventive treatment vary but the visual prognosis for the patient also varies greatly.

Two forms of ocular hypertension can be foretold from the preglaucomatous condition: first, the acute, shallow-angle type with the manifestations of acute decompensation; and second, the chronic, deep-angle form, with its insidious onset. The conditions of the eye before the onset of either form are entirely different, and in many cases can be recognized easily without recourse to provocative tests. It is of the utmost importance that such differentiation be made as complete as possible; for in one case provocative tests could lead to irreparable disaster, whereas in the chronic form such tests may be made with impunity. In consequence, a careful clinical study is indicated as the first measure.

As the knowledge concerning ocular hypertension has progressed in the past 25 years, it has become recognized that

an impending disturbance of ocular-pressure balance causes certain signs and symptoms that can be detected upon careful search. In as much as nearly 20 percent of all blindness is due to glaucoma, it behooves the ophthalmologist to suspect the possibilities of that condition in every patient past the age of 30 years; and his examination of all such patients should include those aspects which, if suspicious, would warrant further investigation with a view to determining whether preglaucoma exists. But such precautions can be carried to excess, and to perform elaborate provocative tests upon all patients is just as senseless as to neglect them in suspicious cases. What, then, are the appearances that should indicate further investigation as to the existence of a preglaucomatous state?

First to be considered are the eyes that may develop acute hypertension. The history that can be obtained from the patient is of great significance, greater than in the chronic type. The description of prodromal attacks of acute hypertension, lasting from one-half to three or four hours, is, as a rule, so characteristic that the diagnosis is obvious. Furthermore, the history of pain developing after an emotional or physical disturbance or after a stay of upward of 15 minutes in the dark, occasional halo vision, decreased visual acuity, moderate injection of the eyeball, gastric disturbances, or partial shock with spontaneous recovery, is of utmost significance. Only a limited number of preglaucomatous patients have had prodromal attacks, but other significant features can be elicited. Headaches that appear with fairly constant regularity after 10 to 15 minutes in a dark room,

* Presented at II Pan-American Congress of Ophthalmology, at Montevideo, Uruguay, November, 1945.

such as at a cinema, are of importance. A slight decrease in dark adaptation, as noted by an intelligent patient, may be of diagnostic significance but is not common.

Such patients are seldom under 45 years of age or more than 70. Refraction plays a far greater role in eyes likely to develop acute than it does in those that will develop a chronic glaucoma, as myopia, even of a moderate degree, is seldom present. A moment's reflection will recall the fact that the myopic eye is larger than the average normal in antero-posterior measurements, and in consequence the anterior chamber is deeper and the angle of the chamber is less acute. Goniometric measurements by Sugar and myself have shown the mathematical value of the angle in myopia to be greater than that in hyperopia, usually. In consequence, there is less possibility of blockage of the trabeculum by the root of the iris; in fact, the danger of chamber-angle occlusion is negligible in the wider-angled chambers. Following the same line of reasoning, it can be understood that there are certain types of irides that can easily block the chamber angle; namely, those in which the antero-posterior thickness is somewhat greater than the average and in which pupillary dilatation can cause an undue increase in antero-posterior thickness of the iris root. In every eye in which there is the anatomic predisposition to acute glaucoma, there exists a definite threshold of pupillary dilatation. By that is meant that when the pupil dilates beyond the given threshold of that eye, it is accomplished by such an increase in the antero-posterior thickness of the root of the iris that there is formed a blockage of the chamber angle and of the trabeculum, with the consequent acute rise in intraocular pressure. As yet there is no means of determining what that threshold is in the individual eyes. For

that reason, certain provocative tests are definitely contraindicated in the preglaucomatous stage of the acute-glaucoma type.

In patients who have had definite prodromal attacks, remains of such attacks may be seen in one or both of two forms. The first is a slight irregular dilatation of the pupil, usually upward, and involving about one quarter of the periphery, as though there had been a partial paralysis of the sphincter pupillae, which probably had occurred. The second is a partial sector-shaped disappearance of the iris stromal chromatophores, resulting in a limited area of light decoloration. This has been seen in blue irides, but is more common in the darker brown ones. Never is there the complete washed-out appearance that so frequently persists after an actual, acute attack. This pigment disturbance must not be confused with the Koeppel pigment-granule appearance that is found so frequently in compensated glaucoma.

To recapitulate briefly, when a patient in the fourth, fifth, or sixth decade of life presents a history suggestive of real, prodromal attacks or a history of headaches developing after a short period of absence of light, or after emotional excitement, the eyes should be examined most carefully from a standpoint of preglaucoma of the acute type. The depth of the anterior chamber, the estimation of the mathematical value of the angle of the chamber, the size, shape, and reaction of the pupil, and the appearance of anomalies of pigmentation of the iris must all be taken into account. Abnormalities of the visual fields, either central or peripheral, need not be looked for, for field changes do not occur. Neither will there be variations in tension from what may be the normal for that eye. Visual acuity will not be disturbed except by any refractive error that may be present.

If the suspicions of the ophthalmologist are sufficiently aroused, certain provocative tests may be undertaken; but they are less apt to yield positive information than similar tests in preglaucoma of the chronic type. Under no circumstances should provocative dilatation of the pupil be performed except in a patient with a highly suspicious eye who lives so far away from ophthalmologic care that an acute attack would spell certain blindness before relief from the hypertension could be obtained. But taken by and large, the diagnosis of preglaucoma of the acute type is dependent rather upon the experience of the ophthalmologist than upon positive information given by provocative tests.

When the ophthalmologist has decided in his own mind that he has to deal with a preglaucomatous condition of the acute type, it becomes his function to institute measures aimed at preventing an acute attack. If the chamber angle is very acute and if there have been prodromal attacks, the use of miotics alone as a preventive measure probably will not suffice, and the patient will have to be persuaded that his visual future depends upon preventive surgery. Peripheral iridectomy, freeing at least 25 degrees of the entire chamber angle, will prevent further hypertension. The iridectomy should be bilateral. But if there have been no prodromal attacks and if the chamber angle is not too acute, miotics will, as a rule, be adequate to prevent acute hypertension. However, it is just as great a mistake to use miotics of too great concentration and at too frequent intervals as it is to use no miotic at all. A solution of 1-percent pilocarpine should be instilled in both eyes at bedtime, as well as before any period of use of the eyes in the dark, such as at the cinema. The patient must be told of the dangers of pupillary dilatation and how this can be

avoided by the use of the miotic, in order that there may be intelligent coöperation on his part.

Considerably more clinical acumen is required to detect preglaucoma of the chronic type. Primarily, the history affords but few clues, for there have been no acute attacks nor headaches nor disturbed visual acuity. In some intelligent patients a definite story of decreased dark adaptation can be elicited, but that is not constant. In a large percentage of cases, heredity plays a definite role, and frequently the patient knows of definite glaucoma in a parent or a sibling. Consequently, with the lack of a definite anamnestic aid, the suspicion of preglaucoma must come objectively. The range of age is much greater, for chronic glaucoma of the compensated type is not uncommon in the third decade of life (or even earlier—I recall one case in a myopic girl of 13 years) and may appear at any time as long as the person lives. Refraction does not seem to play any role of importance, as hyperopia is present in 65 percent of the cases and myopia in 35 percent. That is approximately the comparative percentage of refractive errors in normal individuals of the same age group in this country. The depth of the anterior chamber is usually that which may be considered normal for the patient's age, with the single exception that under mydriasis the chamber has a tendency to become slightly shallower. When examined gonioscopically, the angle of the anterior chamber is always open and usually has a mathematical value typical of wide-open angles. In other words, there is no indication of possible blockage of the angle by the iris root. In some cases there may be a slight increase in the pigment granules or dust, seen so frequently on the surface of the trabeculum. Likewise, there may be the Koeppe pigment dotting of the surface or anterior

stroma of the iris, a finding that is suspicious but not diagnostic.

The pupil tends readily to dilate somewhat unduly, but the reactions are normal, even to the hippus-like reaction that occurs when the narrow beam of the slitlamp falls upon the pupillary border. In some cases (the percentage is not yet known) exfoliations of the anterior capsule of the lens are present, and while these are not to be taken lightly, still the presence of that condition is not absolutely diagnostic of either glaucoma or preglaucoma. In true preglaucoma of the chronic type, there are no abnormalities in the fundus nor in the optic nerve attributable to that condition.

When the ophthalmologist's suspicions have been aroused to the extent of making a complete perimetric examination, defects of the peripheral fields of a hypertensive character cannot, as a rule, be elicited. In a few cases, slight notching of the inferior nasal field can be demonstrated by the use of a marked reduction in intensity of illumination; however, this finding is not sufficiently constant to justify a routine examination of that type. But in the central fields there is not infrequently a rather significant enlargement of the blind spot of from 1 to 5 degrees. The cause of such enlargement is unknown. It is definitely not due to hypertension, as is frequently the cause in cases of established chronic compensated glaucoma. The other central-field defects that are usually found in chronic glaucoma have not yet made their appearance.

Consequently, when the suspicions of the ophthalmologist have been aroused, the diagnosis of preglaucoma of the chronic type must be established or refuted by provocative tests. Many have been described and practically all are based upon varying amounts of increase in intraocular pressure produced by vari-

ous procedures. Probably the most reliable of all is an increase in pressure of more than 8 mm. Hg, measured tonometrically, as the result of the drinking test or after instillation of a mydriatic; but even this is not characteristic. Positive responses to the various provocative tests are significant, although not absolute, whereas negative responses mean very little if anything at all. So the diagnosis of preglaucoma of the chronic type becomes a function of the clinical acumen and experience of the ophthalmologist, plus some aid from provocative tests.

After such diagnosis has been established, it becomes the function of the ophthalmologist to utilize that knowledge for the benefit of the patient to prevent, in so far as possible, the gradual development of a chronic compensated glaucoma. While this is not always possible, the process may at least be retarded. A weak miotic, usually 1-percent pilocarpine nitrate, may be instilled regularly at bedtime, and this usually is sufficient, although the reason why is beyond our ken. Here, as in preglaucoma of the acute type, the too-frequent use of too strong a miotic may be just as damaging as the complete neglect of the miotic. This latter point must be impressed, especially upon neurotic patients who are apt to run to the pilocarpine bottle upon the slightest provocation.

SUMMARY

Preglaucoma may be divided into two forms: that which may be the predecessor of an acute glaucoma, and that which may be followed by a chronic glaucoma. The two forms can be differentiated clinically and require different types of provocative tests for confirmation. When recognized, preglaucoma necessitates preventive treatment.

58 East Washington Street (2).

SYNDROME OF UVEITIS, MENINGO-ENCEPHALITIS, ALOPECIA, POLIOSIS, AND DYSACOUSIA*

REPORT OF A CASE DUE TO ACTINOMYCES

ROBISON D. HARLEY, LT. COL. (MC), A.U.S., AND
ERLING S. WEDDING, CAPT. (MC), A.U.S.

Ancon, Canal Zone

Ophthalmologists recognize a syndrome of chronic bilateral uveitis in association with alopecia, poliosis, vitiligo, and dysacusia. The following report appears as a slight variation of this clinical entity. Duke-Elder¹ has presented a classical description of the usual syndrome with an excellent report on the literature. The senior author has seen two cases, both in adolescent individuals. The profound diseased state of the eyes is striking and once seen cannot be easily forgotten.

The uveitis is widespread and insidious, and generally begins in both eyes at about the same time. The exudative character of the choroiditis may lead to retinal detachments, and vitreous opacities increase gradually until an adequate view of the fundus is no longer possible. The usual sequelae of uveitis develop with or without treatment until a pigmentary atrophy is prominent. Following the severe inflammatory process the signs of uveitis gradually abate, often with permanent irreversible changes and considerable destruction to the ocular tissues.

Alopecia areata involving the hair of the head, eyebrows, and lashes frequently occurs in a matter of weeks after the uveitis. Poliosis (whitening of the hairs) occurs in a high percentage of cases.

Duke-Elder² states that vitiligo and temporary deafness, lasting four to six weeks, occur in about half of the cases and come on soon after the eye symptoms. Hamada³ appears to have been among the

first to call attention to the central-nervous-system involvement with headache, vomiting, spinal-fluid lymphocytosis, and increased pressure. The disease is apparently self-limiting, although the course may be a matter of months.

The etiology of the disease has been given as unknown, and the treatment considered as entirely symptomatic. Toxic, virus, and allergic theories have been advocated.

Hague⁴ has given an excellent review of the subject and has presented an additional case showing a transient encephalitis. The relationship between the neurodermatoses (alopecia, vitiligo, and poliosis) and the intraocular-pigment disturbance is noteworthy. The role which the hypothalamus plays in organic-pigment disturbances of this nature is well presented by the aforementioned writer. That the encephalitis might affect retino-hypothalamicohypophysial vegetative fibers which control pigment seems likely. In a case of a tumor of the third ventricle⁵ pressing upon the hypothalamus, similar diffuse pigment disturbances were noted. There is good evidence that any irritative action in this region of the hypothalamus may produce this spotty depigmentation.

Hague also draws attention to the similarity of the uveitis syndrome and sympathetic ophthalmia with respect to symptoms and histologic features. There is some evidence for a virus etiology for both ocular conditions but substantial proof has been scant.

In Givner's⁶ case, aqueous and iris tis-

* From the Eye and Ear Department and the Board of Health Laboratory, Gorgas Hospital.

sue produced no virus growth in a series of chorioallantoic and yolk-sac inoculations. He cites several other workers who have had inconstant success with the production of optic neuritis and uveitis from the inoculation of vitreous from affected eyes. No microorganisms were found in the ocular fluids or tissues.

Carrasquillo⁷ has reported carefully on 29 cases which included all the cases other than those tabulated by Koyanagi in 1929. He concluded that a neuropathic factor of sympathetic activity was operative in the uveitis syndrome.

Rosen⁸ found the syndrome of bilateral uveitis, alopecia, poliosis, vitiligo, and dysacusia described in the literature 47 times. He states that the Vogt-Koyanagi syndrome always occurs in darkly pigmented persons. In analyzing the 47 cases for the extraocular signs he reports that alopecia occurred in 31 of 40 cases, poliosis in 43 of 47 cases, vitiligo in 30 of 47 cases, dysacusia in 24 of 44 cases, and cephalgic symptoms in 21 cases.

Hamada⁹ observed 10 cases of acute diffuse choroiditis (Harada's disease), which was first described by E. Harada. However, Hamada states that often these cases were accompanied by meningeal symptoms; that is, headache and lymphocytosis in the cerebrospinal fluid. Vestibular, cochlear, skin, and hair changes were also noted. The uveitis in all cases was diffuse, without distinct nodular formation. The fundi first exhibited localized multiple retinal swellings due to edema, especially distinct about the disc and macula. In a few days the edema fused and a distinct neuroretinitis could be observed. In 7 of the 10 cases a retinal detachment was present. These fundus changes disappeared gradually after two or three months, leaving a fine mottling in the fundi. The central nervous system, vestibular, cochlear, cutaneous, and hair manifestations were observed either be-

fore, during, or after the ocular symptoms became apparent.

Hamada histologically examined those eyes with this form of acute, diffuse choroiditis. He found the proliferating modifications of the uvea manifested by gradual destruction of the pigmentary cells (chromatophores). Pigmentary granules were frequently found in the epithelioid and giant cells in a phagocytized form. After one to three months it was noted that the proliferating and exudative modifications had disappeared and the structures had become atrophic.

The distinction between acute diffuse choroiditis (Harada) and the syndrome of uveitis, vitiligo, poliosis, alopecia, and dysacusia (Vogt-Koyanagi syndrome) with or without meningo-encephalitic signs does not appear clear cut.

On the other hand, the clinical appearance of sympathetic ophthalmia compared with the uveitis in the syndrome of alopecia, vitiligo, poliosis, and dysacusia is striking.

Exudative retinal detachments, poliosis, and deafness have been noted as occurring in sympathetic ophthalmia. Systemic symptoms indicating meningeal involvement have also been observed in sympathetic disease (Snellen,¹⁰ Risley,¹¹ and Luque¹²).

It would appear that there is a common denominator in all three forms of this chronic uveitis.

The following case report of uveitis in association with meningo-encephalitis, alopecia, poliosis, and dysacusia illustrates the profound effect that the disease has upon the eyes as well as on certain other systems. The clinical appearance of the eyes might easily pass as sympathetic ophthalmia and perhaps it may be but a variation of this condition.

The recovery of *Actinomyces* in this case was so clearly proved to us, both from direct smear and animal inocula-

tion, that we felt it was worthy of report.

Sympathetic ophthalmia has been explained as an anaphylactic phenomenon through sensitization to the uveal pigment. It is suggested that in our case the organism, *Actinomyces*, began the ocular inflammatory state which resulted in uveal-pigment destruction. The liberated pigment antigen may have then initiated the anaphylactic process which resulted in further pigment break down in the eyes, hair, skin, and ears. If it is true that some pigment¹³ occurs in the basilar membrane of the labyrinth, then disturbance of this pigmented structure could explain the dysacusia.

The idea that the liberated iris pigment sets the stage for the anaphylactic process which results in a severe bilateral uveitis is not new. The missing link in the puzzle has been what liberates the pigment. In the nontraumatic form of this severe uveitis it has been found that *Actinomyces* can at least act as one of the initial causative agents. The uveitis in this syndrome may be likened to a nontraumatic form of sympathetic ophthalmia.

CASE REPORT

The patient, a Puerto Rican soldier, aged 19 years, was first seen as an outpatient at an overseas general hospital about January 1, 1944, complaining of a severe frontal headache and loss of appetite. His familial and past personal history were unrevealing except that the patient stated that he had been bitten by a scorpion about two weeks prior to the onset of his symptoms. About January 6th the headache lessened, but soreness of the left eye and blurred vision were experienced. Two days later soreness and blurred vision of the right eye were noticed. His visual loss steadily increased, so that in a few days he was unable to read. He stated that his vision was normal on entry into the Army. Chills, nau-

sea, vomiting, and dizziness developed, and he was admitted to the hospital on January 14, 1944.

Physical examination. Examination on admission revealed dilated pupils which responded poorly to light. The scleral and conjunctival vessels were moderately congested, and there was a horizontal nystagmus on left lateral gaze. The disc margins were reported as indistinct, and the retinal veins appeared congested. There were no hemorrhages nor exudates. The nasopharynx was moderately congested. The remainder of the general and neurologic examination showed no abnormal alterations. The temperature was 97°F., and the respiratory rate was 18 per minute. The blood count was 4,520,000 red blood cells; 8,700 white blood cells; hemoglobin 85 percent; polymorphonuclear leukocytes 72 percent, and lymphocytes 28 percent. Urinalysis was normal.

Course in the first hospital. The patient's condition seemingly improved after admission to the hospital. The appetite increased, vomiting ceased, and he became ambulatory. The temperature remained between 97° and 98°F.

Two days later he again vomited. Inspection of the fundi on January 17th showed a bilateral papilledema. A lumbar puncture yielded clear fluid under 12 cm. of water pressure. There were 215 cells per cu. mm. and they were all reported as lymphocytes. The spinal-fluid sugar was normal, but the globulin was slightly increased. X-ray studies of the sinuses showed hazy antra, bilaterally. The maxillary sinuses were irrigated. The fluid return from the left antrum was clear, but that from the right was of a dark straw color. The culture from the right antrum showed hemolytic *Staphylococcus aureus*. On January 23d a bilateral, inferior retinal detachment was noted. The nystagmus on left lateral gaze persisted,

but otherwise no additional neurologic findings were uncovered. Vision was 20/200 O.U.

The senior author first saw the patient in consultation on February 9th. The presence of bilateral, inferior, symmetric retinal detachments was confirmed. There were many small, discrete, yellow and grayish spots in the periphery of both fundi which appeared to be multiple areas of focal chorioretinitis. There was an optic neuritis, bilaterally, measuring approximately 2D. elevation. The slit-lamp showed many keratitic precipitates and cells in the aqueous, bilaterally. The ocular picture alone resembled a bilateral, subacute neuroretinitis and uveitis with retinal detachments. The symmetry of the detachments was striking. The vision continued to become obscured because of the haziness of the media. The patient was given a course of sulfadiazine for eight days and then seven intravenous typhoid injections. The latter gave excellent fever responses. Four more spinal-fluid analyses were done, and the cell counts (reported as lymphocytes) ranged from 214 to 142 on March 3d. No polymorphonuclear cells were ever noted. Aside from a persistent slight increase in the globulin, the cultures, Wassermann tests, gold curves, and Queckenstedt's sign were repeatedly negative. The blood counts remained nearly the same as on the first examination; the white blood count rarely was found to be above 8,000. A blood culture showed no growth. Two sedimentation rates were identical at 3 mm. in one hour. Two blood-serum specimens were negative for lymphocytic choriomeningitis. Blood smears failed to show malaria parasites or microfilaria. Stool examination showed no parasites or ova.

Course in the second hospital. The patient was transferred to Gorgas Hospital, Ancon, Canal Zone, on March 30, 1944. Ocular examination showed that the haze

in the media had increased markedly. Vision was: O.D., perception of hand movements at one foot; O.S., finger counting at two feet. Keratitic precipitates and cells in the aqueous were seen in profusion. The elevation of the retinas could still be observed.

No new neurologic changes had been added at this time. Spinal-fluid cell counts

Fig. A (Harley and Wedding). Alopecia as noted at the end of 3½ months of illness.

on April 3d and 6th showed 30 and 20 cells present, respectively. Other spinal-fluid examinations, including cultures, were negative. Examinations for toxoplasmosis were negative.

By April 15th the retinal detachments were seen to have reattached, although the view was very poor, indeed. On April 25th, after approximately 3½ months of illness, several large areas of alopecia on the scalp were noted (fig. A) and it was at this time that the syndrome of uveitis, alopecia, poliosis, and dysacusia with meningo-encephalitis was diagnosed.

X-ray films of the skull were negative; of the chest and hands were negative for Boeck's sarcoid. The antra continued to show thickened membranes with straw-colored fluid returns and were treated by Proetz displacement. No vitiligo had been noted, even under ultraviolet-light inspection. The alopecia developed rapidly, and by May 1st the patient was three-fourths bald. Approximately half of the hairs of the eyebrows and eyelashes became white

in a few weeks. Spinal fluid and aqueous-chamber fluid were withdrawn and injected into laboratory animals (rats) on April 15, 1944. Tinnitus was complained of by May 1st. Audiograms done in April and June were within normal range, but in September another audiogram showed a definite nerve-type deafness.

Although atropine had been used topically for months the irides became plastered to the lenses and the pupils remained

hung over the pupillary area, and membranes had grown over both anterior surfaces of the lenses. The keratitic precipitates had diminished in number. Both eyeballs were soft to palpation. In the pupillary center of each cornea in Bowman's membrane was an irregular, yellowish, foamy collection appearing as an early degenerative corneal change, possibly an early band-shaped opacity.

In November 9th and December 28th

Fig. B (Harley and Wedding). Reproduction of left eye after one year of illness. Note the posterior synechia, secondary cataract, flattening of the iris pattern, and neovascular formations on the diseased iris. The cornea is the seat of a bandlike opacity.

in mid-dilatation. Secondary glaucoma developed in the left eye but was controlled by paracentesis. Later both eyes remained in hypotony.

By June 1st the hair on the head was beginning to return, but one quarter of it came back white. Treatment over a period of nine months at Gorgas Hospital has consisted chiefly of administrations of penicillin (400,000 U.), intravenous typhoid, heavy doses of salicylates, diathermy, and topical atropine. No treatment has been of any avail.

An eye examination on November 6, 1944, showed a moderately deep scleral injection, especially about the limbus. There were seclusio pupillae and extreme iris atrophy, since light concentrated on the sclera was easily seen through the muddy brown irides. Vascularization of the iris was prominent, but no nodules were present. A heavy gelatinous exudate

the spinal-fluid cell count was 3, all of which were lymphocytes. The spinal-fluid glucose was 72 mg. per 100 c.c. and sodium chloride was 745 mg. percent. An electrocardiogram was normal. The basal metabolic rate was +6. Blood serum failed to agglutinate stock cultures of *Brucella abortus* in any dilution. More fluid was aspirated from the aqueous chamber of both eyes for further laboratory study on November 6th. Ocular examination on January 23, 1945, showed an increase in the band-shaped opacity in both corneas (fig. B). It was more dense and had assumed a chalky white color and completely replaced Bowman's membrane in the lower third of the cornea. The gelatinous exudate in the aqueous had largely disappeared, but many keratitic precipitates remained. The irides, synechiæ, and cataracta complicata were unchanged. Light projection was some-

what faulty. There were two areas of alopecia, with graying hair returning in the lower occipital region.

The patient had suffered from a chronic rhinitis, catarrhal ethmoid, and maxillary sinusitis accompanied by a eustachian-tube obstruction since hospitalization. Allergy tests with 19 common allergens were made but only pyrethrum was moderately positive. Skin tests for coccidioidin,* histoplasmin,* and tuberculin in both first and second strength were all negative.

Since the patient would require a long convalescence, he was sent to the continent for further disposition. It is anticipated that cataract extractions may be attempted when the ocular inflammation has fully subsided.

BACTERIOLOGY AND MYCOLOGY†

The aqueous humor from each eye was withdrawn in sterile syringes and each placed immediately in a sterile test tube. Similar precautions were taken with the spinal fluid. The following condensed report of the laboratory findings is given:

Direct smear from eye. The grossly cloudy and somewhat granular-appearing fluid aspirated from the anterior chamber of both eyes showed on direct smear diffuse areas with innumerable small coccoid and small rodlike structures. They were predominantly of a purple color but also of basophilic appearance with Giemsa's stain. Some forms were spherical in contour and measured about 2 micra in diameter. A few bodies showed a definite budding form and measured about 2.0 by 4.7 micra at the largest dimensions (fig. 1). Two photographs showing mycelial elements recovered from the aque-

ous humor directly and from the culture of the meninges of an inoculated rat will be shown in another paper. Some purple and basophilic staining round bodies and rodlike structures appeared to be within the acidophilic staining cytoplasm of some of the cells. These cells had large basophilic staining, vesicular nuclei. A few slightly basophilic staining and septate nonbranching mycelial filaments were observed. Basophilic amorphous precipitate was also seen. Control smears for foreign material in stains showed no such similar structures.

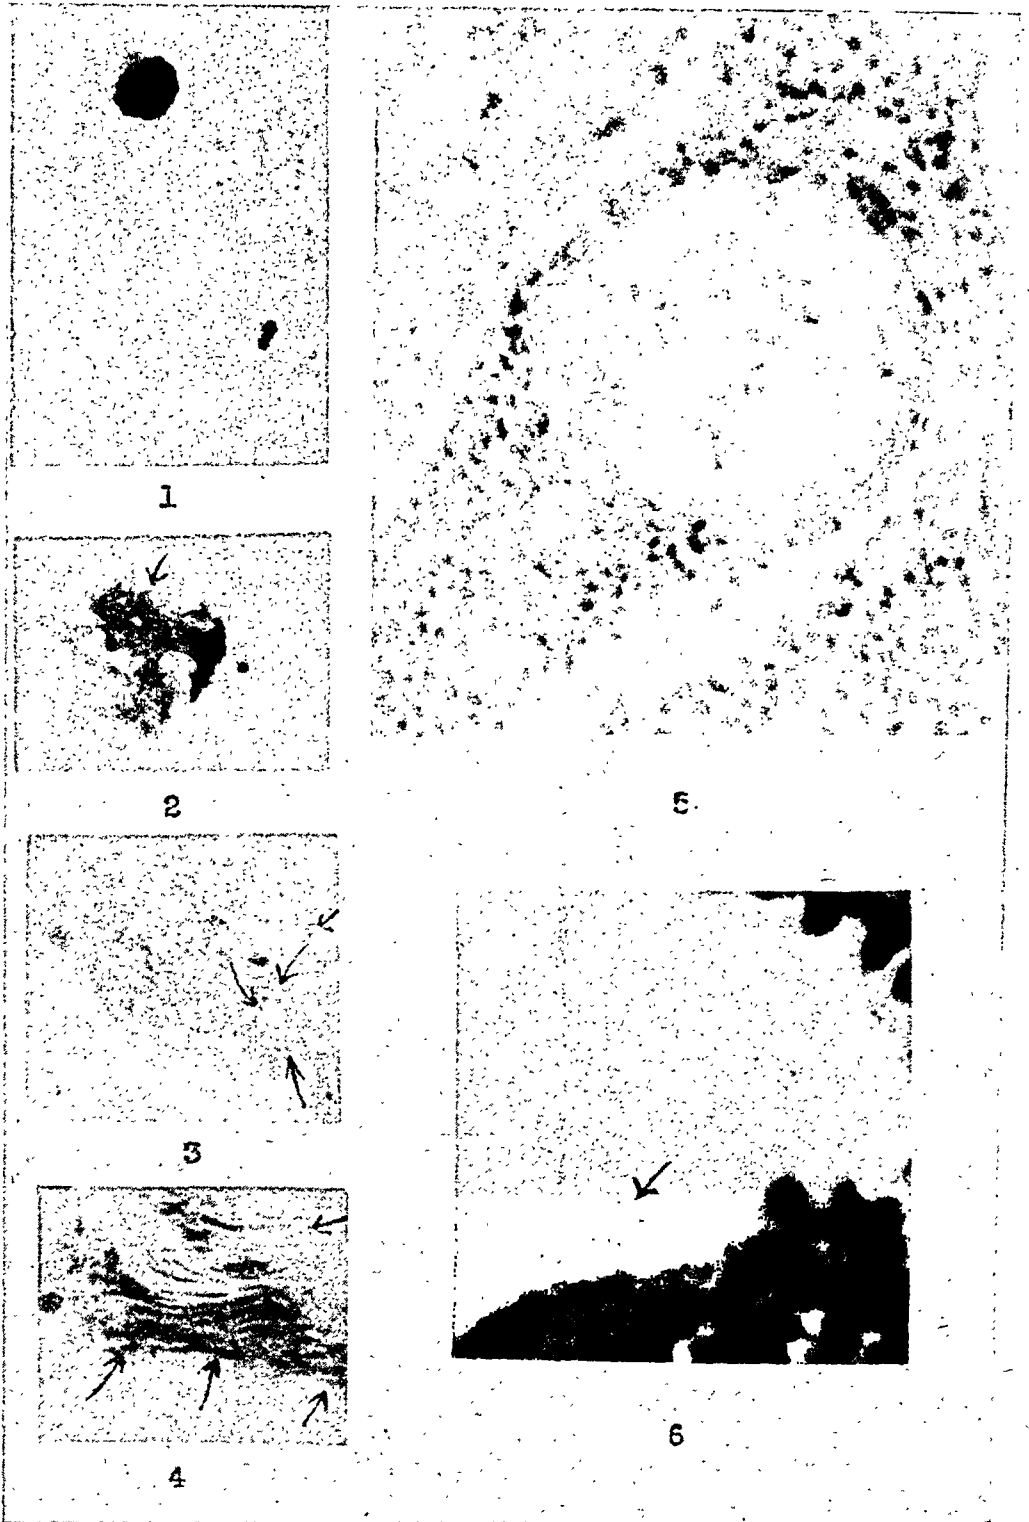

Direct examination of spinal fluid. Unfortunately, the spinal-fluid specimens were examined late in the course of the disease in this laboratory. The heavy turbidity reported at a previous hospital was at no time observed here. All spinal-fluid specimens were clear except for some red blood cells in one specimen. The maximum cell count was 30 lymphocytes per cu. mm. in the clear fluid. Smears stained by Giemsa's method and prepared from centrifuged specimens showed a few small rodlike and coccoid structures (fig. 2). These forms occurred isolated and in small groups and necessitated extensive search on numerous slides from various specimens. The stain varied from a deep basophilic to a purple appearance. Control smears were negative.

Cultures. Cultures from both aqueous humor and spinal fluid specimens were sterile aerobically and under CO₂ tension, although they were held for some time.

Animal inoculations. Fluid from the anterior chamber of the right eye was inoculated intraperitoneally into a female rat (no. 1) on April 15, 1944. The rat was killed October 8, 1944, and showed grossly mesenteric nodular structure, not recognized as any definite organ (fig. 9 a.). Numerous small pus pockets were situated over the surface.

* The coccidioidin and histoplasmin antigens were furnished by J. F. Kessel and C. W. Emmons, respectively.

† Acknowledgement is made to Dr. H. C. Clark of Gorgas Memorial Laboratory, R. de P., for use of photomicrographic equipment.

Figs. 1-6 (Harley and Wedding). Photomicrographic studies.

Fig. 1. Budding structure, as observed by Giemsa staining of direct smear from aqueous humor of the eye ($\times 950$).

Fig. 2. Rods (see arrow) and coccobacilli, stained by Giemsa's method, the direct smear from spinal fluid of patient ($\times 950$).

Figs. 3, 4. Cocci at different focus levels, as observed in hyalinized mass of cerebral cortex of rat no. 2 inoculated with spinal fluid of patient ($\times 950$; H. & E. stain).

Microscopically the mass was shown to consist of uterus, tubes, and ovaries, with focal and diffuse areas of inflammatory reaction over uterus and tubes and within the lumina of the tubes (fig. 7). Basophilic-staining cocci, diplococci, cocci in chains, and occasional diphtheroid structures were observed predominantly in the serosal exudate (fig. 8). A few cocci were seen within the lumina of the fallopian tubes and a few others were within polymorphonuclear leukocytes.

Spinal-fluid specimens of April 3 and 6, and of May 5, 1944, were all inoculated intraperitoneally into a second rat (no. 2) which was killed on June 30th. Uterus, tubes, and ovaries showed an irregular mass resembling the same structure described for rat no. 1 (fig. 9 b). No pus pockets were present over the external surface of this structure; but surfaces made by sectioning showed small pockets containing a yellow, viscid, and purulent-appearing content. The meninges presented a small, soft, gray nodule, the size of a small pinhead. Direct observation on a preparation from this nodule showed a few small rodlike structures.

Microscopic examination of a section of the lung presented a small abscess well walled off adjacent to some blood vessels and somewhat distant from the larger bronchial ramifications (fig. 5). The uterine cavity and lumina of the tubes were dilated and filled with inflammatory cells (fig. 10). Only a few microorganisms in the form of diphtheroid structures of basophilic staining were seen within the lumina of the tubes, uterine cavity (fig. 11), and ovarian follicles (fig. 6). Occasional basophilic cocci and diplo-

cocci were also present within the uterine cavity. An adjacent lymph node showed almost complete loss of architectural structure with focal areas of abscess formation. A section of the brain showed on the surface of the cortex a small zone of an eosinophilic-staining hyaline mass containing several basophilic-staining cocci and occasional diplococci (figs. 3 and 4).

A third rat was inoculated cisternally on November 6, 1944, with aqueous fluid aspirated from both eyes. This rat died in 24 hours, probably as a result of trauma to the central nervous system.

Cultural characteristics. Cultures were made aerobically and under CO₂ tension on Sabouraud's medium, blood slants, and in hormone broth. All aerobic cultures from both animals were sterile. Cultures grown under CO₂ tension from pus pockets over the external surfaces of the tubes and uterus of the rat inoculated with aqueous humor showed the same characteristics as the cultures grown under CO₂ tension from brain, meninges, and pus pockets of the uterus and tubes of the rat inoculated with spinal fluid. These cultures grew on blood slants and in hormone broth. Colonies varied from pinpoint in size up to pinhead. They were soft and of a gray to a gray-brown color. Sabouraud's cultures were sterile. In 24 hours the predominating structures were cocci, diplococci, and streptococci that took the gram stain variably but for the most part gram positively. Occasional filaments were observed after 48 hours. In 72 hours cultures under CO₂ tension showed acidophilic-staining branching filaments and predominantly basophilic-staining rods in addition to the forms de-

scribed (figs. 12-15). Some of the rods presented a resemblance to the morphologic appearance of those found in direct smear of the spinal fluid of the patient. Twenty-four-hour transplants of cultures grew but died within 72 hours, and further observations of developmental characteristics were not possible.

Correlation of findings. It is already well established that most pathogenic forms of *Actinomyces* are microaerophilic and that some of the pathogens in

this group are aerobic. There are various references in the literature that club formations are neither a criterion for, nor diagnostic of, *Actinomyces*. Emmons¹⁴ considers actinomycosis as an infection caused by invasion of the host by some of the species of *Actinomyces*. He also makes reference to variations of abnormal forms of this organism in culture. Kessel and Goolden¹⁵ refer to the diagnosis of actinomycosis by branching filaments and bacillary forms. The difficulty experienced in

culturing the microaerophilic pathogenic forms of *Actinomyces* with subsequent loss of culture is a common occurrence. Pus from actinomycotic lesions that has been cultured on artificial media frequently shows no growth. The morphologic structures of actinomycetes simulating cocci, streptococci, and rods, together with branching filamentous forms, as is observed in the various developmental stages of the organism, have repeatedly been mentioned in literature. Novak and Henrici¹⁶ and Sartory and Meyers¹⁷ refer to a filterable form of the actinomycetes. Negroni¹⁸ refers to the flexed bacillary forms and the undulant filaments with short ramifications.

The organism recovered from the various lesions of the inoculated animals described in this paper has been classified as one of the species of *Actinomyces*, due to the observed developmental stages terminating in branched mycelial elements. It is important to note that specimens taken from the aqueous and spinal fluid when injected into separate animals produced a similar gross and histologic appearance of the involved structures with the recovery of the same organism from each of the two animals.

All specimens used for cultures and animal experimentation were handled only by the authors with utmost precautions to prevent contamination of specimens. Test tubes and syringes were sterilized twice immediately before being used. Aqueous humor aspirated from the eyes remained in the respective syringes and the syringes were immediately placed in sterile test tubes. No intermediary containers were used. Within a brief time the fluid was inoculated on media, into a rat, and placed on a slide for a smear which was protected in a sterile Petri dish. Spinal-fluid specimens were handled with equal care and precautions. Control smears were made for the presence of

possible contaminants in the stain. Fresh culture media were incubated 24 hours before being inoculated in order to guard against possible contamination in the process of making slants.

It is impossible to say from direct smear alone that a certain early stage of development of an organism is a particular organism. This can be done only by following the development of that organism and by observing its classified characteristics. The developmental stages of the *Actinomyces* mentioned in this paper will be discussed in somewhat greater detail in a separate paper.¹⁹ Further work is being done on a strain of *Actinomyces* recovered from animal experimentation in another case of severe meningitis. The round bodies, sproutlike or budding forms, and other structures mentioned in this paper have also been observed in the aforementioned case in which the organism has been kept viable.

SUMMARY

A syndrome of uveitis, meningoencephalitis, alopecia, poliosis, and dysacusia with the case report is presented.

This syndrome is probably closely allied to that form of uveitis ordinarily associated with alopecia, poliosis, vitiligo, and dysacusia.

A brief account of the reviewed literature is given.

Actinomyces were recovered from the aqueous and spinal fluid and studied by direct smear, animal inoculation, and culture.

It is suggested that *Actinomyces* from the aqueous in this case initiated the pigment liberation from the irides which resulted in pigment sensitization of the uveal tract and possibly other pigmented structures.

The fact that the organism was similarly obtained from the spinal fluid presents the possibility that the pigmentary

disturbance was of central origin in the uveitis in this syndrome and in sympathetic ophthalmia is striking.

The clinical resemblance between the *Gorgas Hospital*.

BILATERAL UVEITIS WITH RETINAL DETACHMENT, POLIOSIS, ALOPECIA, AND DYSACOUSIA

JOSEPH LAVAL, M.D.
New York

On May 22, 1944, Mrs. I. S., 42 years old, white, a resident of New York City, presented herself with the complaint of difficulty in reading small print. She had never used glasses; her general health was good, she stated, except for a recent allergic dermatitis of the lids, due to cosmetics, which her dermatologist was treating.

Examination was entirely negative except for a few cells in the aqueous of each eye, more in the left. Vision O.D. was 20/25 improved to 20/20 with +0.25D. sph. \approx +0.50D. cyl. ax. 90°; O.S. 20/30 improved to 20/20— by +0.50D. sph. The patient read the smallest print by the addition of +1.25D. sph. to each lens. However, the few cells in each anterior chamber as seen with the slitlamp could not be explained, inasmuch as both eyes were white, there was no photophobia, and no ocular complaints other than the difficulty with near vision. The intraocular pressure in each eye was 18 mm. Hg (Schiøtz).

The patient was put on 1-percent parendrine thrice daily, so as not to interfere with her accommodation and thus allow her to continue with her work as a secretary. When she was seen again, four days later, the cells in the aqueous had not increased, the vision was the same, but the fundi now showed an unusual picture. Both optic discs were hyperemic, the margins were fuzzy, and the lower half of each retina was quite yellowish. On the following day, the patient noticed "a big black spot" in front of each eye, and it was found that there was a central scotoma for colors in the right eye and an absolute central scotoma for colors and form in the left eye. The vision was

O.D. 20/30 with +1.25D. sph. and O.S. 20/50 with +2.50D. sph.; the hyperopia had increased. There was still no anterior injection nor change in the cell content of the aqueous. The fundus picture was changing, however, and edema was present at both maculas.

Dr. Brandon found moderate involvement of the antra, and it was decided to have these opened. On May 30th, the day the patient was admitted to Manhattan Eye, Ear, and Throat Hospital, her vision was O.D. 20/60 with +3.50D. sph. and O.S. 20/60 with +5.00D. sph. She had been using atropine for the past week, and the pupils were well dilated. The edema of the retinas had advanced, causing an increase in total hyperopia of 3 diopters O.D. and 4½ diopters O.S.

On June 5, 1944, five-days after the sinuses were opened, the visual loss and retinal edema had progressed, so that now a +5.00D. sph. was necessary for the right eye and +8.00D. sph. for the left eye to obtain 20/60 vision. Now, for the first time fine deposits were seen on Descemet's membrane with an increase of cellular contents in the aqueous of each eye. The margins of both discs were obscured, and the retinas were edematous and yellow; they bulged forward, so that one had the impression of looking into a funnel with the optic disc at the narrow end.

The patient was admitted with a tentative diagnosis of Vogt-Koyanagi syndrome to the Eye Service at Mt. Sinai Hospital, where thorough laboratory investigations could be carried out. When she was admitted on June 14, 1944, the findings were as follows:

Vision O.D. 5/200—, with +4.00D. sph., 20/70; O.S. 2/200, with +7.00D.

sph., 20/100—1. Hypotony was present in each eye. In the right eye were found slight ciliary injection, conjunctival hyperemia, many fine pigmented keratitic precipitates, 4 plus flare, numerous formed elements in the aqueous, pupil dilated and fixed (atropine). The pupillary margin of the iris presented numerous fine fibrinous posterior synechiae, and there were two small Koeppe nodules at the 3-o'clock position. The lens capsule was covered with a very fine dusting of fibrin and pigment particles, the lens showing only rare cortical spoking. The anterior vitreous showed many small colorless opacities. The fundus presented a marked vitreous haze and pronounced retinal edema. The left eye showed similar changes with more precipitates.

The history elicited on admission revealed that the patient had noted photophobia three months ago. For the past three weeks she had had a gradual loss of visual acuity of both eyes with rather frequent headaches. For the past few days visual difficulty in the upper fields was noted, with slight impairment of hearing.

Course. Several days after admission a symmetric bullous detachment of both retinas inferiorly was noted, but no tear was observed. A lumbar puncture after admission showed 725 lymphocytes, with a total protein of 74 and a negative culture. At no time did the patient show meningeal nor any other neurologic signs. During her stay the spinal fluid gradually cleared of cells. Loss of hair and some loss of hearing also became apparent. The eyes showed little change except for increased haziness of the vitreous and decreased vision. However, for the last week of her stay there seemed to be some improvement despite a few days of exacerbation of symptoms. The patient had moderate ocular pain, malaise, and some fever. Both spinal fluid and aqueous

were taken for virus studies and animal inoculations, the results of which are described by Dr. Lubkin as follows:

The procedure used was the inoculation of a mixture of 0.1 c.c. of aqueous with 0.5 c.c. of spinal fluid into the anterior chamber of a rabbit and two guinea pigs, the bathing of the scarified corneas of two mice (white) with the same mixture, and the injection of aqueous alone into the anterior chamber of one rabbit. All were done bilaterally. The amounts injected were 0.05 c.c. into the rabbits (each eye), 0.01 c.c. into the guinea pigs.

All animals were autopsied. One rabbit died within four days of a febrile illness. The others died within the following month (or were killed) without any suggestive ocular or meningitic symptoms or autoptic findings, with the exception of one eye of one mouse. The apex of the cornea became cloudy centrally and remained so for three weeks due to a deep keratitis with exudate in moderate amount in the anterior chamber and some iritis. The exudate consisted of fibrin, lymphocytes, and a goodly number of polymorphonuclear lymphocytes. There was likewise mixed cells in the adjacent cornea, which was slightly edematous. Nothing suggestive of inclusion bodies was observed even in the Giemsa-stained slides. The epithelium of the cornea seemed to have regrown in this region. The animal was otherwise asymptomatic. The impression was that the animal's keratitis was based upon secondary infection and that the entire series was negative. Dr. Schwartzman received specimens of aqueous and spinal fluid for virus studies and reported them as all negative. Cultures of the spinal fluid were negative; the serum showed no agglutinins against *Brucella abortus* and *melitensis*. The electron microscopy of the aqueous and spinal fluid showed no viruslike bodies.

Treatment. During the patient's stay at Mt. Sinai Hospital, the therapy was as follows: A full course of penicillin, 700,000 units over five days, was given. Four courses of maintained intravenous typhoid-fever therapy were administered, temperatures above 104°F. being maintained for at least four hours after each injection. Local treatment for the iritis and attention to foci of infection includ-

alopecia and grayness of the few hairs left on her scalp. There was no vitiligo and none was found at any time by Dr. Behrman even with the ultraviolet light, using Wood's method. The left globe was slightly injected, the pupils were irregularly dilated and adherent to the lens capsules, much pigment debris was on the capsules with many deposits on Descemet's membrane, and there was a cellular

Figs. 1 and 2 (Laval). Excised iridic tissue from a case of Vogt-Koyanagi syndrome. The tissue is extremely necrotic so that it is quite friable and stains very poorly. There is a moderate amount of round-cell infiltration with an occasional plasma cell. Some hyaline degeneration is present, but there is no thickening of the vessel walls. No tubercles, giant cells, nor inclusion bodies are present.

ing the sinuses were continued. However, there seemed to be no definite response to any of these, and it was felt that the patient would have to sustain the natural course of the disease.

On August 18, 1944, the tension was 40 mm. Hg (Schiøtz) in each eye; the vision was O.D. 20/200, O.S. 20/400, not improved by glasses. There was moderate poliosis of the lashes of each upper lid, the eyebrows were entirely gone, with marked

aqueous. The fundi were visualized with some difficulty, but one could observe that the areas of detachments below were quite flat and the retinal tissues here were washed out and thinned. A blood transfusion of one pint was given on August 30th.

On September 1st the tension was O.D. 43 and O.S. 50 mm. Hg. On September 8th a modified Lagrange operation with complete iridectomy was performed on

the left eye at Manhattan Eye, Ear, and Throat Hospital; the histologic description of the excised iris is given in figures 1 and 2.

There was surprisingly little reaction to the operation, with only a small hyphaema which was absorbed rather quickly. Twelve days postoperatively the tension was O.S. 18 and O.D. 35 mm. Hg. The vision was O.D. 20/50 with $-1.00D.$ sph. (no more plus lenses were necessary now that the retinal edema had subsided) and O.S. 20/400 not improved. The patient was given atropine daily for the left eye, no drops for the right. On October 3d another pint of whole blood was given by transfusion. On October 12th the tension was O.D. 55 and O.S. 15 mm. Hg. Pilocarpin 2 percent was given every two hours for the right eye, but the tension did not fall below 45 mm. Hg.

On November 9th a modified Lagrange with complete iridectomy was performed on the right eye, and there was no post-operative reaction at all. The iris tissue that was excised was similar to that obtained from the left eye. Due to allergic dermatitis from the atropine, scopolamine was ordered for both eyes and the tension continued at 15 mm. Hg, O.U. The patient gradually became allergic to scopolamine and 10-percent neosynephrin was given to be used once daily. By December 19th the vision was O.D. 20/50 with $-1.00D.$ sph., and 20/200 O.S. with $-0.75D.$ sph. The cells in the aqueous were diminishing, and the deposits were fewer. The fundi could be seen quite clearly and the reattached retinas were pale yellowish pink with irregular pigment mottlings. On February 7, 1945, the vision was O.D. 20/40 and O.S. 20/100; on May 10, 1945, it was O.D. 20/30—1 with $-1.75D.$ sph., and 20/100 O.S. with $-0.75D.$ sph. The patient read Jaeger 3 with a $+3.25D.$ sph. add O.U. The eyebrows were slow in growing back, but

the hair on the scalp had improved remarkably in color as well as in amount. The lashes were quite black again.

COMMENT

There have been many reports of uveitis associated with poliosis, dysacusia, alopecia, and vitiligo. Another report would have nothing to recommend itself except in so far as some new observations could be added. In this particular report there are at least two contributions of interest, one clinical, the other pathologic. The clinical observation is unusual in that the patient was seen so early in the course of the disease that the only abnormal finding was a few cells in the aqueous. The pathologic contribution consists of a study of the iris tissue of each eye of the patient. A possible third point of interest is the spinal-fluid findings and the studies made on the aqueous of one of the diseased eyes. This has been done before, but so infrequently that I believe only four other investigators have reported spinal-fluid examinations and only two others aqueous examinations.

Vogt was the first to call attention to the syndrome, but Koyanagi was preceded by several others. It is true that Koyanagi added dysacusia and alopecia, but the condition had been recognized and treated for some time before Koyanagi's paper appeared. One should not ignore the work of Gilbert, Elschning, Erdmann, and Komoto. So-called Harada's disease is the same condition without involvement of the anterior uvea. And one should remember that not all cases have all the factors of the syndrome; one or more may be missing but still the diagnosis is made.

In 1910, Gilbert, in discussing his case, suggested that a herpetic lesion might be the causative agent. Investigators today are still looking for a virus as the possible etiologic factor. In 1911, both Komoto

and Erdmann supported Gilbert's theory when they discussed their own cases. In 1929, when Koyanagi presented his paper, he could add nothing to the etiology or the pathology, but he did add two additional signs to the syndrome; namely, alopecia and dysacusia, which may occur in some of the patients. In 1930, Takahashi carried out some animal experiments and came to the conclusion that a virus was responsible, a concept possibly similar to that entertained for sympathetic ophthalmia or herpetic lesions; again no further advanced than Gilbert's concept in 1910. In 1939, Magitot and Dubois-Poulson had a case in which there were cells in the spinal fluid and "thought" it was due to a virus. In four of Takahashi's six cases the spinal fluids were positive; that is, they contained cells. Malbran and Muhlmann thought their case of Harada's disease was due to a "neurotropic virus" similar to the causative agent of herpes or sympathetic ophthalmia. In Salus's case grayish nodules were present in the iris, and he performed an iridectomy to relieve increased intraocular pressure, but he does not report an examination of the excised iridic tissue. Givner did report on the excised iris tissue and found evidence of chronic inflammation with an occasional eosinophile. Wexler's case was unique in that the vitiligo developed in a

Negress and was quite extensive, but there was no complete laboratory examination.

The two recent attempts to isolate a virus, by Givner and by Hague, both proved to be fruitless as did the attempt in my case. I agree with Hague that the answer lies in the fact that we take the material from the patients too late in the course of the disease. In my case, the aqueous should have been used as soon as the retina began to look edematous, at least six weeks before it actually was used, and the same holds true for the spinal fluid. Hague's and Rosen's recent reports were all-inclusive and remarkable examples of thorough and painstaking clinical effort and literary research.

Inasmuch as the iris tissue shows no lesion characteristic of any particular type of infection, nor any evidence of local virus infection as we understand it today, we must admit that we are no further advanced in our understanding of this disease entity than we were 35 years ago. I doubt that pathologic examinations of an entire globe will throw any further light on the etiologic factor. The future advances lie in better and earlier methods of utilization of the pathologic fluids and tissues obtained from patients with this disease entity.

136 East Sixty-fourth Street.

THE INFLUENCE OF VEHICLES AND FORM OF PENICILLIN AND SULFONAMIDES ON MITOSIS AND HEALING OF CORNEAL BURNS*

GEORGE K. SMELSER, PH.D.
New York

The extensive use of locally applied sulfonamides and penicillin on wounds has stimulated investigation of the effect of these compounds on the regenerative capacity of the injured tissues.¹⁻⁴ In a previous communication,³ it was shown that although chemotherapeutic agents did inhibit the regeneration of corneal epithelium following burns and abrasions, some compounds (sulfadiazine and penicillin) caused practically no inhibition of the healing processes when applied in therapeutically useful concentrations. This conclusion was qualified by the form and vehicle in which the compound was administered; that is, powder, solution, or ointment. It was noted, for example, that sulfonamide powders were more detrimental to healing than lanolin-base ointments of the same compound. It appeared that the size of the particles of these powders might be an important factor contributing to the delay in healing. In addition, our earlier experiments showed that the frequent application of aqueous penicillin solutions (500 Ox.U./c.c.) to the abraded or burned cornea did not inhibit regeneration of the epithelium. Leopold and La Motte,⁴ investigating the effect of penicillin solutions on the abraded rabbit cornea, came to the same conclusion. These authors demonstrated that the application of penicillin ointments, 500 Ox.U./gm. in carbowax base, produced a satisfactory concentration of this drug in the aqueous humor; however, no obser-

vations were made on the effect of penicillin ointments on regeneration. The use of penicillin ointments is becoming very extensive, and since it has been shown (Leopold,⁴ Bellows⁵) that they produce a high concentration of the drug in the anterior portion of the eye, experiments were undertaken to determine the influence of penicillin, in ointment and also powder form, on the ability of epithelial cells to divide and migrate following extensive corneal burns.

The present communication, therefore, deals with the evaluation of: 1. several ointment and powder bases relative to their effect on healing; 2. the role of particle size of sulfonamide powders in the inhibitory effect these compounds have on wound healing; and 3. the effect of penicillin ointments and powders on the healing of corneal burns.

The influence of these drugs and vehicles was determined on both of the major processes involved in the healing of epithelial injuries, cell division, and migration. It has been shown that cell division is active during the period of cell migration following thermal burns.³ The methods used were essentially the same as those reported earlier. Thermal burns of both corneas of rats were produced by the application of a Shahan thermophore (71°C. for 5 seconds). The terminal of the thermophore was shaped to fit the rat's cornea. The burn produced was a 1.5-mm. band extending horizontally

*From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University.

The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Columbia University.

from limbus to limbus. Bowman's membrane was left intact, but the epithelium was killed and sloughed away under the action of tears and lids in two to three hours. Normal healing was rapid, the defect being nearly covered in 12 hours and completely covered with epithelium in 15 hours. If both eyes were left untreated it was found that the injuries healed at an equal rate.

The average residual area of the right and left eye of the control burns varied only 7 percent, 12 hours after the injury was made. The material to be tested was applied to one eye once every two hours. The powders were applied generously and evenly so that the entire cornea was covered. Some residual powder was found in the lower conjunctival sac two hours after such an application. The ointments were also applied in excess, and the animal held for one minute after each application to permit the material to reach all parts of the conjunctival sac. In those experiments where the effect of a drug incorporated in a base was to be tested, the other eye was treated with the ointment base alone. Male rats of the Sherman strain, six weeks of age, and weighing 80-100 gm. were used. The operations were performed in the morning, and the eyes treated throughout the day. Twelve hours after the burn had been made the rats were autopsied and the eyes fixed for histologic study. Accurate camera-lucida drawings of the extent of the unhealed portion of the burn were made at this time and their area was determined by planimeter measurements of the drawings. The eyes were then sectioned, and the mitotic figures in the epithelium were counted. The number of figures in the treated and control corneas were compared, and the difference expressed in percent of the control eye. The number of mitotic figures found in bilateral untreated burns did not differ significantly

in any of 12 cases studied, and the average of the group was only 0.8 percent. The mitotic-figure counts in the powder experiments were made from flat whole mounts of the cornea stained with Harris's hematoxylin. The fixative and stain were used as recommended by Buschke, Friedenwald, and Fleischmann.⁶ After fixation, the corneas were dehydrated, stained, and mounted in Diaphane. The cedarwood oil step and mounting medium used by these authors were omitted; the counts were made in two to three strips extending across the entire width of the cornea and bisecting the band-shaped burn at right angles. The width of the strip of epithelium counted was outlined by an Ehrlich stop, aperture 4 mm. placed in the $\times 10$ eye piece. A $\times 43$ objective was used.

EXPERIMENTAL

The effect of particle size of three sulfonamides on epithelial regeneration was studied. The standard thermal burns were made on both eyes of a series of 32 rats, and sulfonamide powders were applied as aforescribed, a very fine powder (<325 mesh) to one eye and a coarser (100-200 mesh) to the other. The coarser powders were the same size as those used in previous studies.³ The fine sulfathiazole and sulfadiazine powders were the "microcrystals" of those drugs, and the fine sulfacetimide powder was obtained by grinding in a mortar.*

The previously reported inhibition of healing by sulfonamide powders was confirmed, but with sulfathiazole and sulfacetimide this inhibition was definitely less when fine powders were used (fig. 1). The results were very consistent, and favorable in 8 of the 10 pairs of burns

* Our thanks are due to Dr. E. Henderson and Schering and Company for the generous supply of sulfacetimide used in these experiments.

treated with the fine powder of each drug. The average unhealed area of burns treated with the coarser powders was 42 percent and 73 percent greater than in the burns treated with very fine powders of sulfacetamide and sulfathiazole, respectively.

Contrary results were obtained with sulfadiazine, for in these experiments the burns treated with the fine powders healed

burns was treated with fine powders of substances which were presumably non-toxic compounds. Calcium carbonate, zinc oxide, and lactose powders of particle size <325 mesh were used. They are relatively insoluble so that the osmotic pressure of the tears would not be greatly increased. In these experiments the powder was applied to one eye and the other left as an untreated control. All of these

Fig. 1 (Smelser). The area, in sq. mm. $\times 900$, of the unhealed portion of standard thermal burns treated with fine and coarse powders of sulfonamides and control substances. The fine and coarse sulfonamide powders were applied to the right and left eyes, respectively. The calcium carbonate, zinc oxide, and lactose powders were applied to the right eye of each animal, the left eye was the untreated control burn. Each column represents the average based on 10 or 11 experiments for each sulfonamide; 5 to 7 rats were used with each of the inert powders and 18 for the control burns.

at a somewhat slower rate than did those receiving the coarser material. The difference in the healing of the coarse- and fine-powdered burns was not so great (-27 percent) as was found with the other drugs, and the difference was not statistically significant.

It is obvious that at least two major factors are involved in the delay to healing caused by these powders. One may be chemical and due to the nature of the compound itself, and another the mechanical factor of solid particles eroding the thin, freshly regenerated epithelium.

In order to determine the effect of the mechanical factor of particles, a series of

powders delayed epithelization (fig. 1); zinc oxide and calcium carbonate caused the most retardation. Lactose was the least harmful, having an inhibitory effect comparable with petrolatum. Calcium carbonate delayed healing to about the same degree as did finely powdered sulfacetimide, and the delay caused by sulfathiazole and sulfadiazine was comparable to that caused by lactose. It would therefore appear that the mechanical factors in these sulfonamide-powder applications are the main ones which inhibit healing.

The number of dividing cells in the regenerating epithelium was not affected by the application of lactose, CaCO_3 , or

ZnO powders. The difference in number of mitotic figures seen in the treated and untreated eyes was not greater than that found in a control series of bilateral untreated corneal burns.

These data suggest that sulfonamide ointments containing the drug as a finely divided powder suspension would not greatly delay healing. Ten-percent sulfa-

layed healing slightly less than did sulfathiazole.

OINTMENT BASES

Six ointment bases, suitable for ophthalmic use, were studied in the same manner as were the powders. Each base was tested on 5 to 7 pairs of corneal burns. Hydrosorb* and aquafor were used

Fig. 2 (Smelser). The number of mitotic figures found in regenerating corneal epithelium treated with various ointment bases, 12 hours after a standard thermal burn. The difference in the number of mitotic figures found in the epithelium of the treated and untreated control eye of the same animal is expressed in percent of the control eye. The control bar shows the difference between the number of mitotic figures found in untreated burns of the right and left eye of the same animal. Each ointment was tested on 5 or 6 animals.

diazine and sulfathiazole ointments were prepared, using "Micraform" crystals (<325 mesh) in hydrosorb base. Bilateral standard thermal burns were made on the corneas of 12 rats. The sulfonamide ointment was applied to one eye and the ointment base to the other every 2 hours for 12 hours. Healing was delayed in both eyes of all animals; however, the delay in the sulfonamide-treated eyes was not much greater than in the eyes treated with the base. Sulfadiazine de-

without the addition of water. Carbowax 1500 was selected because its consistency was suited to ocular application. A hydrous lanolin base was prepared by incorporating one part of a 1.5-percent NaCl solution in three parts anhydrous

* Hydrosorb (Abbott) is a mixture of oleic acid ester and amide of diethanol amine, oleic acid, and white petrolatum. Carbowax compound 1500 (Carbide and Carbon Chemicals Corporation) is a polyethylene glycol. Aquafor (Duke Laboratories, New York City) is a mixture of petrolatum, wool fat, and cholesterol.

lanolin. The petrolatum-lanolin base consisted of 75-percent soft petrolatum, 20-percent anhydrous lanolin, and 5-percent 1.5-percent saline, by weight.

These bases appeared to be well tolerated by the burned eyes of the rats, except carbowax, which seemed to cause some discomfort. The animals made more effort to rid themselves of this material

thelium (fig. 2). There was a very slight average decrease in the number of mitoses seen in petrolatum- and carbowax-treated eyes, but this difference is without significance. The epithelia treated with ointments containing lanolin showed, on the average, more dividing cells than did the controls, but there was considerable variation between the individual animals. The

Fig. 3 (Smelser). The effect of various ointment bases on epithelization of corneal burns. The bars represent the unhealed area of the treated burns, 12 hours after the injury, relative to the area of the untreated control burn of the same animal. The area is expressed in percentage of the area of the untreated control burn which is represented by 100. Each bar is the average of 5 or 6 cases.

than of the others. Carbowax differed from the others because of its solubility in tears. An amount of carbowax which covered the eye and filled the conjunctival sacs dissolved in one or two minutes in the tears. It may be that the material itself stimulated tearing. Some difficulty was found in making petrolatum adhere to the ocular epithelia, but this was overcome by softening the petrolatum with the addition of a few drops of mineral oil.

None of the ointment bases interfered with cell division in the regenerating epi-

thelium. The increases found, 20-25 percent, are on the borderline of statistical significance.

All of the ointment bases inhibited epithelization to some extent; however, some were far more harmful than others (fig. 3). Hydrosorb-treated burns healed the most rapidly. Petrolatum, lanolin, and their mixtures were moderately inhibitory; the unhealed portion of the burns treated with these ointments were twice the size of the untreated control burn at the 12-hour stage. Carbowax and aquafor inhibited epithelization the most; the residual burn area of these groups av-

eraged $2\frac{1}{2}$ -3 times that in the control eye. It is obvious upon reference to figures 2 and 3 that epithelization may be delayed in the absence of a decrease in mitosis. It is clear that hydrosorb possesses advantages in both its effect upon cell division and migration. Second choice of ointment material based on these factors would in-

cillin was finely ground in a drop of mineral oil with a glass rod; this fine suspension was thoroughly mixed with soft petrolatum to make the desired concentration. (3) Penicillin, in the free acid form,* was ground in a drop of mineral oil with a glass rod and then incorporated in petrolatum; (4) a preparation similar

Fig. 4 (Smelser). The effect of penicillin in ointment and powder form on cell division in regenerating corneal epithelium. The number of mitotic figures is expressed in percentage of the number found in the control burn which received the ointment or powder base alone. Each bar is the average of 6 to 8 experiments.

clude lanolin and petrolatum. Carbowax appeared to be the least desirable on this basis. For these reasons, in the experiments with penicillin ointments, hydrosorb and petrolatum bases were used.

EFFECT OF PENICILLIN OINTMENTS AND POWDERS ON HEALING

All of the penicillin ointments were prepared to contain 1,500 Ox.U. per gram. Four preparations were tested. (1) Ca-penicillin (Squibb) was dissolved in one drop of water (ca. 50 mg.), and this made up to 1 gm. with hydrosorb. (2) Na-peni-

to (3) except that hydrosorb was used instead of petrolatum. The first ointment contained the drug in aqueous solution: in the last three the penicillin was dispersed in an anhydrous medium. In two cases soluble salts of penicillin were used, in the others the penicillin was in a lipid soluble form. Ophthalmic penicillin ointments of this type, but in another base, were introduced earlier (Von Sallmann

* We are greatly indebted to Dr. G. A. Harrop and Dr. Oscar Wintersteiner for the preparation and assay of the free acid penicillin used in these experiments.

and Meyer⁷). All ointments were freshly prepared for each experiment. In the present experiments the penicillin-containing ointment was applied to one burned eye, and the ointment base alone to the other. These four ointments were tested on 24 animals.

The effect of penicillin on mitosis in regenerating corneal epithelium was not marked; however, the number of dividing cells in the epithelia treated with acid

burn areas treated with penicillin or the calcium salt was smaller than that of the controls, but the difference was slight and should not be considered as evidence of stimulation. The unhealed area of the burns treated with the Na-salt ointments tended to be greater than in the controls, but this also is without significance.

PENICILLIN POWDERS

These data show that penicillin does

Fig. 5 (Smelser). The area, in sq. mm. $\times 900$, of the unhealed portion of standard burns treated with penicillin ointments and powder. The areas were measured 12 hours after burning. Each preparation was tested on 6 to 8 animals.

penicillin tended to be slightly greater than in the controls (fig. 4). The Ca-penicillin was without effect. Three of the eight animals treated with Na-penicillin showed definitely fewer mitoses in the treated eye. The same ointments were applied to intact corneas of 14 animals once every hour, instead of at two-hour intervals. The frequency of mitotic figures was not significantly disturbed in any, but mitosis counts tended to be low in the Na-penicillin-treated eyes.

The rate of epithelization of burns treated with penicillin was extremely good (fig. 5). The burns treated with ointments of penicillin, or its salts, healed at essentially the same rate as the control burns treated with the ointment base alone. The average 12-hour-

not interfere with the reparative processes when applied as ointments. The use of penicillin in powder form, to insure very high local concentration, has been suggested⁵ and used clinically.^{8, 9} Therefore, penicillin powder was applied directly to corneal burns. Both eyes of 14 rats were burned, and one eye in each case received a small amount (about 0.5 mg.) of penicillin powder every 2 hours for 12 hours. Eight rats were treated with Na-penicillin and six with the calcium salt. The powder dissolved in the surface film before the animals were released, so that there was no abrasive action of the powder on the regenerating epithelium. The results were extremely bad. The wounds did not heal; in fact, often a larger area of the cornea was denuded at the end of

the 12-hour period than was caused by the burn. No mitotic-figure counts were attempted. The penicillin powders were then applied to the intact corneal epithelium of six animals. In five of these there was definite destruction of the corneal epithelium. The corneas stained strongly with fluorescein, and sections showed that they had been extensively eroded down to Bowman's membrane. Mitotic-figure counts were made in one case in which the erosion was only superficial. The number of cell divisions was normal.

Obviously the use of penicillin powder undiluted is contraindicated. Ca-penicillin powder was thoroughly mixed with lactose (particle size <325 mesh) and the mixture made homogeneous by repeated sieving. Calcium penicillin was chosen because it is not so hygroscopic as the sodium salt, and the preparation available was a very fine powder. Each gram of lactose-penicillin mixture contained 30 mg. of Ca-penicillin or 28,000 Ox.U. penicillin per gram. The lactose-penicillin powder was applied to corneal burns of six animals. The control burns of the same animals were treated with lactose alone. The treatments were at 2-hour intervals, and the powders were applied over the entire cornea. The results (fig. 5) show that the penicillin-lactose powder did not delay epithelization more than did the lactose alone. Furthermore, the use of the very strong powders did not delay healing more than the application of such materials as petrolatum or lanolin.

The number of mitotic figures in these treated burns was also determined (fig. 4). The penicillin-treated eyes tended to have more cells in division than did the control eyes, but the difference was slight. Only one case showed definitely a greater number of mitotic figures in the treated epithelium.

DISCUSSION

In determining the effect of therapeutic agents upon healing, many factors are involved. The accepted beneficial effect of the agent may be in part or entirely voided by damage inadvertently done to the healthy regenerating tissue. The damage may be caused either by the method of administering the drug or by secondary effects of the compound itself. Harm caused by physical factors in the method of administration can be avoided by changes in technique. Inhibition due to the drug itself can be avoided only by substituting another compound or by decreasing concentration or the speed with which the drug is released to the tissues.

The importance of physical factors is illustrated by the effect that particle size of sulfonamide powders had on epithelization of corneal burns. It seems likely that such physical factors are of particular importance in the eye. The action of the lids moving the particulate matter over the intact and actively regenerating epithelium would cause, as has been shown, considerable damage. The inhibition of healing caused by the large particles suggests that powders incorporated in ointment bases should also be very minute. The mechanism by which the coarser powders inhibited healing is not clear. They may erode the epithelium partly with the aid of lid action or they may actually block the forward movement of the cells over the denuded area. This latter does not seem probable, for the finest powders would do this as well. If actual erosion or the formation of minute injuries is involved, probably the shape of the particles would play a role. Another factor is the stimulation of tearing; the tears themselves may influence the processes of healing.

The physical and mechanical factors were obviously not the only ones involved in the inhibition of healing in these ex-

periments. Even though sulfacetimide was applied as a very fine powder it still delayed healing more than the other sulfonamides; likewise, zinc oxide was more detrimental than lactose. These differences may be due simply to the solubility of the compounds and the production of hypertonic media, or to some chemical action on the cellular metabolism.

The selection of suitable ointment bases for ophthalmic use is complicated by the many factors which must be considered. Obviously, the preparation must adhere well, hold the drug without destruction of its activity, and release it to the tissues in effective concentration. The effect of the base on wound healing is an additional factor. In the present experiments it is shown that some ointments delay healing much more than others, but all bases tested delayed healing to some extent. Without a single exception, every burn treated with any ointment base was at least a little larger than the untreated burn of the control eye at the 12-hour stage. In the case of hydrosorb and lanolin the mean difference between the treated and control eyes was not great; in fact, statistically insignificant. The presence or absence of water in the base does not seem to be of great importance, for the lanolin ointment was one-fourth water, and the hydrosorb anhydrous. The means by which ointment bases inhibit healing is not indicated by the present experiments. It is difficult to imagine that they physically block the movement of the cells, for no more than a surface film remained on the eye for any great length of time. Carbowax, which delayed healing the most, dissolved in the tears and appeared to be removed almost completely between applications. The solution of this base may have caused an unfavorable shift in the osmotic pressure of the fluids on the

cornea. It does not seem likely that these varied bases were or contained substances toxic to the epithelium. It is also difficult to believe that they formed a film over the cells which would inhibit gaseous metabolism. The bases conceivably could absorb substances necessary to the healing processes and thus carry them away; however, there are no available data bearing on these hypotheses.

From a practical point of view it is clear that ointment bases alone may delay healing, but that some are less harmful than others. This observation is in agreement with the report of Leopold and Steele.¹⁰ Therefore, a base should be selected from this group provided that it satisfies the other requirements outlined above.

The experiments with penicillin ointments confirm the result of our first series, that penicillin, in this form, was almost completely harmless to the reparative processes of the corneal epithelium. Application of the very strong ointments caused no detectable inhibition in the repair processes of either mitosis or cell migration other than that due to the ointment base. No real difference, in this respect, was found between the several ointments tested. This is in agreement with the clinical observations of Crawford and King,¹¹ who, however, used much weaker penicillin ointments. The decrease in number of mitotic figures found in the epithelium treated with the sodium-salt ointments, although suggestive, was too slight to be regarded as significant; however, it should be pointed out that this preparation slightly delayed epithelization also.

Although penicillin in ointments did not significantly delay healing in these experiments, the application of penicillin in other forms may cause marked harm to the corneal epithelium. The intact cor-

nea cannot tolerate even minute quantities of penicillin powder applied directly. Owing to the solubility of these powders it seems certain that the damage is not caused mechanically. The effect of such local application of penicillin to healing burns was disastrous, for the epithelium not only failed to heal but some of the unburned portion was sloughed away. Again the effect could not have been due to mechanical action of the particles. Use of penicillin powders in this manner is definitely contraindicated. Anhydrous penicillin powders, however, may be applied if the penicillin is sufficiently diluted, as was shown in the experiments with lactose-penicillin powders. The use of powders has the advantage that the penicillin is almost instantly dissolved and an aqueous film of very concentrated penicillin solution covers the epithelium. This film is held for some time by the lactose particles which are permeated by the penicillin solution, and may act as an infinite number of minute lamellas.

SUMMARY

1. The size of the particles of sulfonamide powders applied to injured corneal epithelium is an important factor in the delay they cause in healing.

2. Powders with particle size < 325 mesh inhibit healing the least. When the particle size is 100-200 mesh, marked inhibition results.

3. Sulfadiazine and sulfathiazole powders inhibit the healing of corneal burns

less than does sulfacetimide powder.

4. Sulfadiazine and sulfathiazole powders do not inhibit healing more than presumably inert powders such as ZnO or CaCO_3 .

5. Finely powdered lactose inhibited healing less than any other powder tested, and hence is suggested as a vehicle or diluent.

6. Ointment bases varied in the degree with which they inhibited the healing of corneal burns. Hydrosorb and lanolin were the least harmful.

7. Application of penicillin ointments (1,500 Ox.U./gm.) did not retard epithelization or mitosis in corneal burns more than the ointment bases alone. This was true of both hydrous and anhydrous ointments, particle suspension and solution types, as well as ointments prepared with the free acid of penicillin or its calcium salt. Very slightly less desirable results were obtained with a Na-penicillin-powder suspension ointment.

8. Solid penicillin (Ca or Na salts) applied in minute amounts markedly harms both normal and burned corneal epithelium, completely preventing the healing of corneal burns.

9. Ca-penicillin powder, suitably diluted with lactose (28,000 Ox.U./gm.), may be applied to corneal burns without inhibiting healing more than would the lactose or petrolatum alone.

OVERSEAS OPHTHALMOLOGY

JOHN W. HENDERSON, MAJOR (MC), A.U.S.

How will the practice of ophthalmology in an overseas theater differ from a civilian practice? While perusing case records collected over a 10-month period in 1944, I found bits of information that might be of interest to those who had not been sent overseas. It seemed worthwhile to report this information and to discuss the problems and trends of ophthalmology as I observed them in New Guinea.

Data for this report were gathered from outpatient and hospital services among general, station, and field hospitals in both combat and rear areas. The patients represented all branches of the armed services but were predominantly members of the Army Air Corps and Army ground forces. Approximately 2,400 individuals registered for the first time in the eye departments of these hospitals during the 10-month period. For convenience of discussion the subject matter was divided into six sections; namely, refractions and ocular-muscle problems; so-called diseases of the external eye; ocular conditions produced by trauma; neurologic and medical problems associated with the eyes; surgical procedures; and equipment and supplies.

REFRACTIONS AND OCULAR-MUSCLE PROBLEMS

The majority of the patients, some 1,450 (60 percent of the total), were registered in the refraction department because of complaints referable to an alteration of visual acuity or because of headaches. The diminution or blurring of vision was associated either with reading, working in the sun, attending movies, syncope, or dizziness. Such symptoms were similar to those met with in civilian practice except for the frequent implication of the tropic sunlight. Each patient was given a complete ocular examination, and some type of refraction was performed.

In only half of the cases was there found a refractive error of such degree as to warrant a prescription for glasses. These individuals presented the familiar symptoms of eye fatigue associated with attending movies or doing close work and usually obtained relief by the wearing of correcting lenses. An exception was encountered among radar operators of air-warning units. These individuals usually worked six-to-eight-hour shifts daily, oftentimes at night. From the description

of their work in addition to the intensity of their ocular symptoms it appeared that this occupation was unusually fatiguing to the eyes. Most of the radar operators had a visual acuity of 20/20 and a refractive error under cycloplegia of less than one diopter in any meridian. Prescribing of glasses did not always bring relief of symptoms. In general, the types of refractive errors among the group to whom glasses were issued were similar to those encountered in civilian practice.

In the 50 percent to whom glasses were not issued, an ocular basis for their complaints was not found. These individuals associated their eye complaints either with dizzy spells, bizarre headaches, or outdoor work in the heat. A history of eye difficulties prior to their service in this area was not often obtained. Many of these soldiers had visited clinics in other hospitals without obtaining relief of their symptoms. In all cases the symptomatology did not seem sufficiently marked nor incapacitating to warrant evacuation from an overseas theater. Their repeated attendance at sick call created quite a problem for the unit medical officer. Most of the patients were dissatisfied that an organic basis for their difficulties was not found.

Many soldiers complained of photosensitivity not associated with dizziness, headache, fainting, or other psychoneuroticlike symptoms. Special attention was given to this complaint because the individual felt incapacitated for outdoor work. With the instruments available, alterations in the corneas and lenses were not seen. Alteration of the pigment content of the maculas was not observed. This symptom seemed equally as frequent in blonds and brunets. Sunglasses of good quality were so scarce that a therapeutic trial was not always possible except in Air Corps personnel. I felt that the efficiency of many ground-force person-

nel would have been improved if a larger supply of sunglasses had been available. In the absence of definite ocular pathologic change one could only assume that the photosensitivity was, in a sense, a physiologic response of the eyes to tropical sunlight.

Flying personnel of the Air Corps were infrequent visitors to the refracting room, although a large number of such personnel were present in this area during the period of this study. The low incidence of visual-acuity complaints among this group speaks well for the screening methods employed in the United States. When such personnel did report with eye complaints, their refractive error, heterophoria, and accommodative and convergence relationships were found to be within the limits of normal. The flight surgeon usually felt that such individuals were suffering from combat and flying fatigue.

Only a few cases of abnormal heterophoria were encountered. These were managed by prescribing appropriate prisms, as was customary in civilian practice. Soldiers seemed more tolerant of prisms than civilians with similar muscle imbalances.

On an average of twice a month a case of subnormal accommodation with or without convergence weakness was encountered. In all of these, difficulty with close work had occurred since the subject's arrival overseas. None had had any other illness. Repeated examinations always revealed a remote near point of accommodation; the near point often approaching that of a presbyopic individual. I was unable to find an etiology. Plus spherical corrections were added to the refractive error as revealed by cycloplegia, and most of the patients obtained symptomatic relief by wearing the spectacles for near work. In some cases simple convergence exercises were recom-

mended, but the soldiers would not persist in such exercises.

Soldiers with nontraumatic, long existent strabismus were frequent visitors to the eye clinics. Because of limited finances the strabismus had not been corrected in civilian life. The soldiers believed that the strabismus could be easily corrected by the Army "docs" and, in addition, would entail no financial outlay. Early in my overseas service I saw about 10 men with strabismus who had been operated on by Army surgeons. All of these individuals presented excellent cosmetic results, but they were disappointed either because there was no improvement in visual acuity or because of onset of diplopia. The diplopia made them of little use to the Army. Those with diplopia knew that if they made enough fuss about their "double vision" they would be returned to the United States. Those in whom visual acuity had not improved had had poor vision prior to surgery. Subsequently, I became cautious about advising surgical correction for a strabismus that had existed prior to Army service. It seemed that proper preoperative selection of these cases had not been seriously considered. However, there was an occasional need for such surgery among personnel with marked comitant strabismus employed as instructors, and personnel with an alternating strabismus who did skilled work. Such individuals were usually non commissioned officers who occupied responsible positions. The few patients whom I selected for surgery were given careful explanations of the probable functional as well as cosmetic result. When they were returned to duty they not only appreciated the improved cosmetic effects but were also cognizant of the limitations to perfect binocular vision.

Interesting cases of unilateral amblyopia ex anopsia were encountered, in some of which there was also a comitant

strabismus of the amblyopic eye. It was noted that these individuals became more aware of their ocular defects after entry into Army service or assignment to overseas duty. They associated an inability to do ordinary tasks, not involving the use of their eyes, with either their defective vision or the strabismus. They gave a history of having consulted several Army oculists and of having had many refractions. A few of them contended they were aware of diplopia, although suppression of the visual image in one eye had existed prior to Army service. In all but one case I was unable to elicit diplopia. These soldiers were apparently attempting to use either the amblyopia or the strabismus as an escape from a disagreeable situation. Most of them were referred to a neuropsychiatrist.

There were no instances of definite or persistent ocular malingering. A few individuals were seen every month who half-heartedly feigned poor visual acuity in a normal-appearing eye. Most of them were Negroes assigned to engineering units. Once these soldiers were shown that their visual acuity was normal they returned to duty satisfied.

A few cases of presbyopia were encountered, but it was possible to handle them without resorting to bifocal lenses.

DISEASES OF THE EXTERNAL EYE

Approximately 500 cases (20 percent of the total) comprised this group.

Chronic, nonspecific conjunctivitis; blepharitis; hordeola; and chalazia were the predominant diseases treated in this group. I came to regard these conditions in this locality as phases of the same disease, the conjunctivitis and blepharitis representing the initial stage and the chalazion the end result. They were observed in both male and female personnel, blonds and brunets, individuals in outdoor as well as indoor occupations. Serv-

ice in this theater seemed a contributing factor, since many of them never before had experienced such ocular conditions. Dust was an ever-present nuisance. Cultures and smears of the ocular secretions from these cases revealed no consistent pathologic organisms. The cases of blepharitis caused the most difficulty. With hospitalization, the severest cases subsided in from four to five days. Once the patient returned to duty the blepharitis usually recurred, and the soldier plagued the dispensary medical officer with a seemingly incurable, chronic disease. However, it did not seem that sufficient attention was given at the unit dispensaries to treatment of the early stages of this disease. With a little more attention to local therapy and local hygiene, these cases could be kept in check, making hospitalization unnecessary. From the standpoint of the time spent on sick call and in hospitals, these diseases were an important problem among Army personnel.

Pterygia occurred in about the same frequency as would be seen in a civilian practice located in an agricultural community. However, pterygia among soldiers were larger and progressed more rapidly. The usual surgical methods for correction of the pterygia were not always successful. An average of one soldier per month came to the eye clinic with a recurrence of the pterygium; some had had several operations. The eyes with recurrences appeared to have had some type of transplantation operation, but the apex of the pterygium was reattached to the surface of the cornea. Several of these individuals had been operated on by competent Army oculists so that it was not a question of skill. I did not have an opportunity to observe after a lapse of several months the cases on which I performed a transplantation operation. Other oculists probably observed recurrences in the cases in which I operated. Some de-

gree of corneal opacity occurred following the transplantation or excision of large pterygia. In the Army service it seems wise to operate on the pterygium as early as possible in its growth period.

Burns of the eye were produced by a wide variety of external agents. Refrigerating fluids, ether, acetone, sulphuric acid, battery acid, chemical smokes, ultraviolet rays from the welder's torch, hydraulic-brake fluid, ignited kerosene, and explosions of gasoline were the causes found among the case records. The emergency care of ocular burns by the unit medical officer was excellent in all cases. With the exception of burns resulting from refrigerating fluids, the corneas recovered their transparency, and there was little impairment of visual acuity. In all cases the burns were bilateral. Burns produced by exposure to the welder's torch recovered most rapidly; burns from refrigerating fluids responded least to therapy. A 2-percent solution of sodium bicarbonate was the most frequently used irrigant. This weak, alkaline solution seemed more soothing to the patient than solutions of boric acid, water, or normal saline. A 2-percent solution of butyn, a 0.5-percent solution of pontocaine, and a commercial type of ointment combining 2-percent butyn and 1:3,000 metaphen were used with equal efficacy for relief of pain. Atropine was routinely instilled. In combat zones, topical analgesics were sometimes not available. Burns produced by explosions of gasoline following aircraft accidents were contaminated with dust, dirt, and pieces of cordite. Recovery from such burns was better than I anticipated.

An interesting case of the last-named type came under observation at a field hospital. Seven survivors of an airplane crash were brought to the hospital with burns of much of the body surfaces. Another Army ophthalmologist and I shared

the care of the ocular burns. In the confusion attendant upon the admission of these patients one individual's eyes were overlooked. This patient remained in a semicoma for six days. Eye therapy throughout this interval consisted of boric or normal saline drops routinely instilled by the nurses. On the seventh day the patient was sufficiently aroused to complain bitterly about pain in his eyes. It was then discovered that he had not been seen by an oculist prior to that time. Upon inspection of the eyes two thirds of the surface area of each cornea stained with a solution of fluorescein. The denuded areas did not appear to extend deeper than Bowman's membrane. The margins of the burned areas were not necrotic. The conjunctivas were of normal appearance. The entire external surfaces of the eyes appeared clean and free from secondary infection. The eyes were patched for 24 hours and the corneal surfaces were soon covered with epithelium. Ultimately visual acuity was normal. It seemed that the simple, mechanical washing of the conjunctivas carried out by the nurses forestalled secondary infection and contributed to the satisfactory outcome.

Acute keratoconjunctivitis was a problem in this area. Clinically the cases resembled those described in the United States as "shipyard conjunctivitis." In half of these cases, cultures of the discharge revealed *Staphylococcus albus*. In the remainder, repeated cultures and smears were negative. The local use of such drugs as sulfadiazine, zinc, argyrol, and mercuric oxide failed to influence the course of the disease. Oral intake of sulfadiazine likewise was of no benefit. Penicillin instilled at frequent intervals into the conjunctival sac seemed to be the most efficacious of all drugs tried. Oftentimes a herpes labialis appeared at some time during the course of the disease. Two cases were associated with a solitary, herpes-

like lesion on one eyelid. In both a typical dendritic keratitis developed. I felt that these cases were caused by a virus, although conjunctival scraping stained with the available dyes did not reveal inclusion bodies. The ultimate recovery was good. From a military standpoint, these soldiers were incapable of duty for from four to five weeks.

Several cases a week were referred from the dermatology department with inflamed conjunctivas and dermatitis of the eyelids. In all of them, there was either an eczematoïd or exfoliative dermatitis of various body surfaces. I found nothing that would cure the eye condition so long as the dermatitis persisted. The local use of penicillin either as an ointment or in solution was the most efficacious in reducing the congestion of the conjunctivas and eliminating the discharge. The discharge from the conjunctivas seemed particularly irritating to the skin of the eyelids. A thin layer of zinc-oxide paste applied to the eyelids after all crusts and flakes were brushed away proved to be the most beneficial therapy for the surrounding skin. Keratitis was prone to develop if eye irrigations were neglected. *Staphylococcus albus*, hemolytic and nonhemolytic streptococcus, and gram-negative bacilli were most often cultured from the conjunctivas.

The remaining external eye conditions encountered were of a miscellaneous nature; for example, corneal ulcers, iridocyclitis, scleritis, blepharospasm, corneal opacities, phlyctenular conjunctivitis, dermatitis medicamentosa of the conjunctivas and eyelids, papillomas, dacryocystitis, and melanomas of the conjunctiva. There was nothing among this group of an unusual nature. The corneal ulcers were the result of incomplete removal of superficial foreign bodies. Progressive, serpiginous ulcer did not occur if the foreign body was completely removed at

the initial visit. The cases of iridocyclitis were mild and fewer than I expected. An unusual type of corneal opacity that seemed peculiar to soldiers serving in the tropics was observed. Observations on this peculiar eye condition have been forwarded for publication.

OCULAR CONDITIONS PRODUCED BY TRAUMA

In contemplation of such a report as this, all ocular conditions produced by trauma were carefully recorded and classified. There were two reasons for this special attention. First, I assumed that ocular trauma would be very frequent among Army personnel. Secondly, I assumed that the factors responsible for the trauma would be far different from those observed in an industrial or civilian practice. Both of these assumptions I found to be incorrect.

Only 170 cases (8 percent of the total number of patients) of ocular trauma were encountered. Of these only 60 (2.5 percent of the total registration) were produced by combat with the enemy. The remaining cases were produced by the hazards common to everyday living.

The ocular injuries received in combat areas were always severe and usually unilateral. Either traumatic cataract, retained intraocular foreign body, panophthalmitis, prolapsed iris, or intraocular hemorrhage was the end result. Bullets, shrapnel, booby traps, and pieces of coral were the offending agents among combat troops. Injuries to the eye unaccompanied by wounds or lacerations of other body surfaces were incurred while the soldier was peeking over the rim of a foxhole. Oftentimes the missile was small and dropped out of the eye by the time the soldier reached an evacuation hospital. The retained foreign bodies were most often nonmagnetic. The Berman localizer helped us to determine the magnetic prop-

erties of the foreign body. The traumatic cataracts were not different from those seen in civilian practice. Iridodialysis was seldom observed. Dislocation of the lens was not seen. Prolapse of the iris was easily corrected in all instances, but these cases were seen shortly after injury. Panophthalmitis developed in about one third of the cases in this group. The incidence of this complication seemed in proportion to the time interval between injury and the first examination by an ophthalmologist. Once panophthalmitis had developed, parenteral, oral, or local use of sulfadiazine and penicillin seemed to have no effect.

In 55 percent of the cases, the factors responsible for the trauma were unavoidable and did not involve contact with the enemy. Detached retinas, contusions of the eye, orbital fractures, and the ophthalmoplegias were incurred in this manner. The cases of detached retinas were seen in Air Corps mechanics who had unwittingly bumped their heads on a protruding part of the airplane. The orbital fractures were usually associated with fractures of the mandible and maxillas. Manipulation of the body and frontal process of the malar bone was the most difficult feature of these orbital fractures. Reduction of the mandibular fracture and occlusion of the teeth were first necessary to secure a foundation on which the other facial bones could be manipulated. I was fortunate in that an oral surgeon was available to carry out these procedures. Ophthalmoplegias were induced by crushing injuries to the head. Function of the external rectus muscle was most frequently impaired; function of the superior oblique was the least apt to be impaired. When more than one ocular muscle was paralyzed, internal ophthalmoplegia was also present. In none of the cases of external ophthalmoplegia did normal muscle function become reestablished

during an observation period of six weeks.

Five percent of the cases of ocular trauma were attributed to carelessness. Individuals so injured were usually members of a detail engaged in cleaning fire arms, working on rifle ranges, or disposing of refuse. The gun that someone said was unloaded claimed many victims. The unsuspected bullet or powder charge that exploded when a pile of refuse was ignited accounted for three of the four cases of ruptured globes. Hammering on shell casings and melting bullets for their lead content were also frequent sources of ocular injury.

MEDICAL AND NEUROLOGICAL OPHTHALMOLOGY

Approximately 280 cases (11 percent of the total) composed this group. In this theater there was an opportunity to examine the fundi of individuals suffering from diseases not usually seen in civilian practice; such as, tsutsugamushi fever, malarial fever, and dengue. Although other ophthalmologists told me that retinal hemorrhages were apt to occur during an attack of tsutsugamushi fever, I was unable to detect any alteration in the retina, optic nerve, and choroid in the 45 cases that I had the opportunity to examine. These cases of "scrub typhus" were examined during all phases of the disease. The fundi were also normal in cases of cerebral as well as noncerebral types of malaria. However, in many of the cases of malaria and "scrub typhus" subconjunctival hemorrhages developed or hemorrhages in the fascial investments of the ocular-muscle tendons. There was nothing in the configuration or the location of these hemorrhages that was peculiar to either of these diseases. Neither was I able to determine in which cases hemorrhages in the external coats of the eyeball were likely to occur. Hemorrhages in the

subconjunctival tissues were frequent with "scrub typhus," infrequent with malarial fever. The hemorrhages occurred with sufficient frequency in the former disease to be of diagnostic significance. The triad of subconjunctival hemorrhages, fever, and lymphadenopathy often proved sufficient to make a diagnosis of "scrub typhus" in early cases, even though an eschar was not found. Aside from the intense retro-orbital headaches and dull pain upon ocular rotation, ocular complications during the course of dengue were not observed.

Although most of the routine fundus-copic examinations proved to be negative, one or two patients a week would exhibit some pathologic lesion. Several cases of acute vasospastic retinitis were seen initially on the eye service, and the patient was subsequently evacuated because of hypertension. Narrowing and sclerosis of the retinal arterioles compatible with a diagnosis of benign hypertension were occasionally observed. Retinitis of anemia was observed among cases of thrombocytopenic purpura, aplastic anemia, and myelogenous leukemia. Retinitis of diabetes was very infrequent, and no fundus-copic changes accompanying either acute glomerular nephritis or meningitis were recorded.

One of the most interesting conditions seen among the group occurred in a flyer who had bailed out over tropic waters. This aviator had floated in the water for three days and three nights before being rescued. According to the patient, his rescuers had commented on the marked swelling of his body tissues. On the medical record accompanying the patient was the observation that massive edema of the subcutaneous tissues of the thorax, neck, thighs, and legs existed. Ophthalmoscopic examination was made for the first time one week following rescue, when much of the body edema had subsided. I

do not recall seeing such extensive edema of the retina as existed in this patient. In the maculas alone there were large circumscribed masses of edema with elevation of the surface of the retina to three diopters. Several branches of the retinal arterioles supplying the macular areas were markedly narrowed, irregular in caliber, and surrounded by dense perivascular sheathing. These changes suggested an ischemic origin of the edema. It was felt that the prolonged immersion contributed to the changes observed in the retina.

About once a month an individual with papilledema was seen. These patients had suffered injury to the skull with either subsequent brain abscess, epidural bleeding, or subdural hematoma. Unequal pupils, nuclear ophthalmoplegias, conjugate deviations, and homonymous defects in the visual field were other ocular findings noted in these cases. In two individuals presenting complaints of headaches, but without previous head injury, bilateral papilledema was found. A provisional diagnosis of brain tumor on the basis of the neurologic and spinal-fluid findings was made.

Visual fields were frequently plotted of individuals complaining of postconcussion headaches. In only one case was a definite defect found in the visual fields. Perimetric studies were also useful to the neuropsychiatrists to corroborate the diagnosis of hysteria.

OCULAR SURGERY

Contrary to my expectations, there was comparatively little ocular surgery to perform. The cases requiring surgery constituted only 2.5 percent of the entire ophthalmologic practice. While working in a general hospital I observed patients on whom ocular surgery had been performed in more forward areas. These represented another 2 percent of the patients. In both field and station hospitals,

there was an opportunity to do more ocular surgery than in a general hospital.

In the field and station hospitals, the surgery was more of an emergency type. Ruptured globes, eyes requiring early enucleation or evisceration, the excision of a prolapsed iris, the management of a corneal laceration, and the repair of lid-margin defects were the problems usually encountered. In general and station hospitals in rear areas, traumatic cataracts, paralytic squints, iris synechiae, ptosis, detachment of the retina, manipulation of fractures about the bony margins of the orbit, and intraocular foreign bodies predominated. Pterygium surgery was common in hospitals of both forward and rear areas.

Much of the surgery performed in this area was done in open buildings. I worked in both open and closed buildings and, except for the factor of dust, it seemed to make little difference whether the operating rooms were closed or open. The incidence of postoperative infections was practically nil so long as the atmosphere was relatively free of dust. In a hospital located adjacent to a dusty, well-traveled highway, I observed that the postoperative course of my patients was not so smooth as in hospitals where the wards and operating room were farther removed from the roads. The eyes of patients who had been evacuated to this hospital from forward areas and who had had eviscerations, lid-margin repairs, or removal of an intraocular foreign body were often infected and their postoperative course was prolonged. These cases had little care enroute, and I believe that was the factor responsible for sloughing of sutures and tissue necrosis.

Except for pterygium surgery, the surgical techniques commonly employed in civilian life were applicable for ocular surgery in war zones. As mentioned in a previous paragraph, the pterygia among soldiers were prone to recur after the

usual transplantation operation. Plastic procedures on the conjunctiva with excision of the growth were necessary more often than in civilian practice. To forestall the recurrence of the pterygium and yet utilize the transplantation technique, I sutured the apex of the growth to the episcleral tissue as well as the overlying conjunctiva at the site of transplantation.

Because most soldiers were evacuated before six months had elapsed from time of injury, plastic procedures for cicatricial entropion and cicatricial ectropion were not carried out. The factor of time also limited the correction of traumatic ptosis. I felt that the ultimate cosmetic result of lid-margin defects was better if surgery was performed early rather than after scar tissue had formed. An occasion for glaucoma surgery did not arise.

The autoclaves and solutions for sterilizing eye instruments were adequate at all hospitals.

EQUIPMENT AND SUPPLIES

In a report such as this it seemed appropriate to discuss the instruments and supplies available to the overseas ophthalmologist. The equipment list for station and field hospitals included an assortment of forceps, hooks, probes, spatulas, keratomes, knives, knife needles, repositors, spoons, speculums, and scissors adequate for all types of ocular surgery. The ocular surgeon in an overseas general hospital was more limited in the scope of his surgery by a similar supply of instruments. Because of the long distances involved in evacuation to the United States and the relative limitation of space on hospital transports, patients often remained in general hospitals for an extended period of time. An opportunity to perform more definitive ocular surgery was thus possible except that some instruments common to the general hospitals in the United States were not provided. The surgical instruments available were

of standard design and of good quality.

The unavailability or shortage of replacements made it important to preserve those instruments which were received. In general, the ophthalmic equipment arrived in good condition. In field hospitals ocular surgery was often performed in conjunction with other emergency surgery. This necessitated the sterilization and mixing of the eye instruments with the larger tools of the general and orthopedic surgeons. Blunting or dulling of the instruments was the inevitable result. In the station and general hospitals this factor of handling was not such a problem. The prevalence of rust in the humid climate of the tropics and the realization that the same scissors and knives would have to be used over a period of several years put a premium on the instruments available to us.

The need for a magnet frequently arose not only in ocular surgery but for removal of particles in other tissues of the body. The magnet I received had been donated by a civilian practitioner. This particular instrument was unsatisfactory for the removal of tiny particles within the eye. Nonmagnetic instruments for use with the magnet were not included with the eye equipment.

An electrocautery with several types of points was received. The dermatologist and general surgeon found this instrument very useful for removal of cutaneous warts and tumors. So far as the eye was concerned some type of fulguration apparatus would have been more useful.

The equipment for refractions was complete except for cross cylinders. Where a large number of refractions are done the cross cylinder adds a great deal to the speed with which the patients can be handled, and for that reason it would be a valuable supplement to the diagnostic case. An additional trial frame would be appreciated, for there are so

many screws and joints to get into disrepair. There was some trouble with mold growth on the trial lenses along the coastal areas of New Guinea. If the trial case was placed in a box equipped with an electric lamp this nuisance was eliminated. The electric retinoscope was satisfactory. Heterophoria was determined with the trial frame, red glass, and Maddox rod. A phorometer was not provided.

Spectacles were obtained from strategically located optical centers. The average elapsed time between requisition and delivery was two weeks. Breakage in transit was negligible. A large variety of lens prescriptions was available for dispensing.

One of the most valuable items was the case for the fitting and repair of spectacles. Lost temple screws, bent frames, and loose nose pads brought many soldiers daily to the clinic. The tools, screws, and extra temple pieces made it possible to salvage the spectacles on the spot.

The ophthalmoscope heads projected a beam of light that was wide in diameter and was not of a make commonly used by the civilian practitioner. Anyone coming overseas should bring his own ophthalmoscope.

I came to regard the slitlamp and perimeter as valuable adjuncts to the overseas practice of ophthalmology. There were many occasions to use the slitlamp, had it been available. A perimeter was not included in the original equipment, but one was obtained from a base supply depot. Other ophthalmologists were not so fortunate.

For several months the hospitals were furnished a small supply of glass eyes. More recently they were collected and redistributed to certain key hospitals in the theater. The fitting and wearing of a prosthesis among patients awaiting evacuation was a big morale booster. The soldier who suffered an enucleation or evisceration was less self-conscious when

he was given a prosthesis before departure.

The hospitals in this area were first established in what was considered a combat zone. The field hospitals and most of the station hospitals were set up beneath canvas. Prefabricated buildings were provided for the general hospitals. Once the buildings and tents were erected, improvisation was necessary to complete the furnishings of the eye clinics.

A dark room was one of the chief needs. For field hospitals and some station hospitals a portable room seemed the most practicable. Pieces of press wood were obtained through local channels and nailed to wooden frames. A room of approximately 6 by 6 by 8 feet seemed adequate. For the general hospital, a dark room 20 ft. in length with sufficient space for a perimeter, slitlamp, and transilluminator was constructed. In the climate of New Guinea, ventilation in these rooms was important. Shielded inlet and outlet air vents were necessary. Still these rooms were too hot for prolonged occupancy. An electric fan easily solved the problem of ventilation, but fans were not a part of the initial equipment and had to be obtained by special requisition.

All of the diagnostic instruments were 110 volts, but the standard current from the generator was actually 240 volts. There were sufficient transformers available to handle the difference in voltage.

Rheostats were provided, and the electric bulbs for most of the diagnostic instruments were used over a long period of time before they burned out. However, the bulbs provided for the transilluminator were not of sufficient voltage adequately to carry the illumination necessary with this instrument. The transilluminator soon became useless for want of bulb replacements.

A wood or cement floor seemed desirable for eye clinics. With hard dirt or gravel floors it was not possible to keep

the eyes and instruments as free of dust as one would desire.

In general, the supply of drugs for use in the eyes was adequate except in the forward areas. In such areas there was a scarcity of topical analgesics such as butyn and pontacaine. Homatropine was another drug not easily obtained. Cocaine was available, but one hesitated to use the drug for expediting the removal of foreign bodies in the cornea. Atropine, the old standby, was always available. An item that found universal use among hospitals, unit dispensaries, and aid stations was a common commercial ointment combining butyn and metaphen. I saw few undesirable reactions in eyes to which this compound was applied. It provided a good deal of comfort to the patient during his transit to an ophthalmologist. It was a useful item for emergency eye therapy. There was little occasion for the use of physostigmine.

Intravenous typhoid vaccine was a very useful agent in the treatment of stubborn cases of conjunctivitis, keratitis, iritis, and intraocular conditions of either endogenous or exogenous origin. Eyes responded to Army typhoid vaccine where all other therapeutic measures failed. However, there was one difficulty. Every bottle of typhoid vaccine I received was long antedated, frequently over six months. I soon discovered that the potency of the vaccine was proportionate to its age. An initial dose of from one to five million organisms was usually adequate. In higher initial concentrations the fever was prone to go above 102°F., a 12- to 18-hour period of fever was apt to occur, secondary and tertiary reactions would appear, and the patient experienced severe chills. Even with such severe reactions I did not see any kidney or liver complications. I feel that Army typhoid vaccine is a safe agent for intravenous use so long as its increased potency is kept in mind.

DISCUSSION AND SUMMARY

The patients from which the data for this report were gathered were a good composite of combat and noncombat personnel. The total number of soldiers examined would probably approximate the average observed in other hospitals in this area over a like period of time. It was not the purpose of this report to formulate definite conclusions but only to comment on the trends of an ophthalmologic practice among such a group of soldiers.

I was not prepared before coming to this area to find that such a large proportion of an overseas practice would be devoted to refractions. Rather I had assumed that my time would be more occupied with the treating of external eye diseases and repairing the effects of trauma. Many of the individuals examined in the refraction room probably would not have consulted an oculist in civilian practice because their eye complaints were so frequently linked up with other bodily complaints peculiar to service in the Army.

Unilateral amblyopia ex anopsia among overseas personnel was more of a problem than among civilians similarly affected. Many of the soldiers had been told they would not be sent overseas. Others cited various reasons why they could not get along overseas so long as they possessed the amblyopia. I felt that unilateral amblyopia ex anopsia was compatible with overseas service so long as the soldier was assigned to tasks in a noncombat area not requiring extensive use of the eyes. Hysterical amblyopia seemed more common among noncombat personnel than in combat troops.

Among the external eye diseases chronic, nonspecific conjunctivitis and blepharitis accounted for the most patients. These diseases were more of a nuisance than a therapeutic problem, and blepharitis, in particular, was responsible

for many soldier hours lost on sick call. Acute keratoconjunctivitis was a problem from the standpoint of prolonged hospitalization and the failure of any local therapy materially to shorten the course of the disease. The etiology of this condition was not satisfactorily determined. Atypical lichen planus and other dermatoses were frequent among soldiers in this area, and secondary involvement of the conjunctiva was not uncommon. Local penicillin therapy was tried for some of the external eye conditions. As a therapeutic agent for local use in the eyes it seemed more efficacious than many of the standard drugs employed in civilian practice, but it was not used in a sufficient number of cases to allow formulation of definite conclusions. Burns of the eyes among soldiers were probably as frequent as burns among civilian personnel working in industrial areas. Prompt treatment was usually possible, and the outcome was uniformly good, except in those eyes that had been burned by refrigerating solutions.

From the limited scope of this survey it seemed that traumatic conditions of the eyes did not comprise a great deal of the overseas ophthalmologic service. Eye injuries as the result of combat, in particular, seemed relatively infrequent. Perhaps the helmet worn by our troops in this war was a factor that influenced the low incidence of eye injuries. The eye injuries among noncombat personnel were produced in a manner not unlike those observed in civilian life.

Medical and neurologic ophthalmology composed but a fraction of the professional work performed by overseas hospital groups. However, when the infrequent need for such examinations did occur, the oculist usually assisted in the

differential diagnosis. The neurologist, neurosurgeon, neuropsychiatrist, and internist regarded the ophthalmologist as a handy man to have around when puzzling cases occurred. In this theater approximately 11 percent of the eye patients were examined from the standpoint of these specialties. The opportunity to examine the eyes of patients suffering from diseases endemic to this theater was of particular interest to me. Objective changes in the eyes did not seem to occur with dengue fever; in malaria they were not frequent. Hemorrhages in the subconjunctival tissues of the cases of "scrub typhus" occurred frequently enough to be of diagnostic significance. Although the pathology of "scrub typhus" is vascular in nature, alterations of the choroidal and retinal vessels did not occur in the cases I examined.

Ocular surgery comprised but a small portion of the eye practice. In view of the hazards of warfare I anticipated that surgical cases would be more plentiful. The types of surgery performed in overseas units seemed to vary according to the distance between the hospital and the combat zone.

In general, the equipment furnished the overseas ophthalmologist was adequate and of good quality. Some improvising was necessary in the construction and furnishing of the eye clinics. The occasional shortage of ophthalmic drugs in forward areas seemed not a matter of supply so much as one of distribution.

From a professional standpoint I found my overseas experience an interesting one. There was a good variety of ocular conditions to observe and treat, and the patients were appreciative of their care.

THE REMOVAL OF ADJACENT NEVI OF THE EYELIDS*

ALSTON CALLAHAN, M.D.

Birmingham, Alabama

The various and ingenious procedures for the repair of deformities of the lids after surgical removal of tumors have always been fascinating. Many of these depend upon the opposing lid for tissues to supply the loss. In the following case report the tumors were adjacent on opposing surfaces of the right lids, and the problem was solved by utilizing a combination of procedures.

A man, aged 21 years, stated that while an infant it was noted that he had a small brown spot on the lower right lid. This spot was located just below the lashes and at about the junction of the middle with

that of the lower (12 mm. by 6 mm., fig. 1). Only at the lid margins did the nevi extend through the entire thickness of the lid, and neither tarsus was involved (fig. 2). A general physical examination revealed no other such nevi, but on the

Fig. 1 (Callahan). Adjacent nevi of the lids. The upper measures 15 mm. by 6 mm.; the lower, 12 mm. by 6 mm.

the lateral third of the lid. This area of pigmentation was not elevated and did not begin to increase in size until about seven years ago. The rate of growth was very slow, and two years ago it extended to the upper lid. When first examined in February, 1945, the nevus of the upper lid was larger (15 mm. by 6 mm.) than

Fig. 2 (Callahan). Adjacent nevi of the lids, with upper lid everted, showing involvement of the margins.

shoulders and upper back there were found many small spots of brown pigment. No melanin was found in the urine.

The first-stage operation was performed on March 12, 1945. Avertin was used as a basal anesthetic, supplemented by novocaine block of the supraorbital and infraorbital nerves. Diathermy cutting current was used to remove the nevi with 3 to 4 mm. of normal tissue surrounding them. The lower nevus was removed first (fig. 3). Dural hooks were used to hold the tumors, and the use of grasping forceps was avoided. The coagulated skin edges and the coagulated mucous-membrane edges were then removed with a scalpel. In the region of the nevi both lids were divided into a posterior lamina of tarsus with mucous

Figs. 3, 4, 5, 6 (Callahan). Steps in the operation for removal of nevi. Fig. 3, The tumors are held with small hooks, the use of grasping forceps being avoided. Diathermy cutting current is employed to divide the nevi from the lids. Fig. 4, The posterior laminae of conjunctivas and tarsi are joined with chromic catgut 4-0 interrupted sutures. The muscle and subcutaneous tissues are partly joined with the same suture material. Fig. 5, Free skin graft, removed from left upper lid, is sutured into place with silk 4-0 interrupted sutures. Fig. 6, Hair-bearing skin graft placed in center of free skin graft. This operation was performed three months following that shown in figure 5.

membrane, and an anterior lamina of skin, subcutaneous tissue, and muscle. The posterior laminae were joined with chromic catgut sutures and the subcutaneous tissues and muscles were then joined similarly (fig. 4). The skin defect was supplied by a free skin graft from the left upper eyelid (fig. 5). To prevent undue tension on the medial extremity of the graft, a Wheeler lid adhesion was placed half the distance between the graft and the nasal end of the lids. To prevent the bed for the graft from shrinking, one tension suture was placed from the upper

lid into the supraorbital tissue and another from the lower lid to the cheek.

Microscopic examination of the tumors revealed clusters of nevus cells and considerable melanin pigment beneath an atrophic epithelium. There was no evidence of malignancy, and the diagnosis was made of benign moles.

The graft grew excellently, and almost the normal degree of elasticity of skin and subcutaneous tissues returned.

On May 28, 1945, the second-stage operation was performed. An incision was made through the skin into the subcu-

taneous tissues across the center of the previously transferred skin graft. The skin edges were slightly undermined. An area of hair-bearing skin, the width including four rows of cilia and the length approximately that of the previous skin graft, was removed from the right eyebrow. This was not rotated, but kept in the same relative position and sutured into the incision created for it (fig. 6). No cilia were planned for the margin of the lower lid, since they are not prominent.

This area of hair-bearing skin grew excellently, but, as is often the case, the cilia present in the graft fell out, a few at a time, with loss of all in about 10 days. In three weeks, however, the hair follicles of the center rows had begun to grow new cilia, and by the latter part of July there was an excellent line of them. On August 3, 1945, the lids were divided just below the cilia.

On August 20, 1945, the patient was discharged with relatively normal lids and a slightly irregular but not conspicuously abnormal lash-line of the upper right lid. The new cilia turn upward, forward, and have an inclination laterally (fig. 7).

Comment. The satisfactory result obtained in this case (compare figures 1 and

Fig. 7 (Callahan). Final appearance after division of lids, performed two months after transplant of hair-bearing skin.

7) encourages the early removal of nevi which show a tendency to growth after a long period of quiescence.

In this case the pathologic report revealed no malignancy; but, in a spreading nevus, a protracted delay would have meant further unsightly involvement of both lids with the necessity of more extensive surgical procedures when finally removed. There is always the possibility, of course, that malignant changes may set in.

THE RELATIONSHIP OF RUBELLA IN THE MOTHER TO CONGENITAL CATARACTS IN THE CHILD*

EVERETT L. GOAR, M.D., AND CHARLES R. POTTS, M.D. (by invitation)
Houston, Texas

In 1942, Dr. N. McAlester Gregg,¹ an Australian physician, called attention to the occurrence of congenital cataracts in infants whose mothers had had German measles in the early months of pregnancy. In 1943, a nationwide investigation was conducted by the National Health and Medical Research Council of Australia.² Dr. Algernon B. Reese³ reviewed the reports of the Australian physicians in 1944 and added three cases of his own.

In Gregg's report, which consisted of 78 cases, 20 of which he had examined personally and the records of the remainder of which he had studied, most of the babies were undernourished and presented feeding problems; all had cataracts from birth, 62 of them bilateral; most of them had heart lesions; all had poorly developed musculature, and the majority had subnormal mentality.

We wish to report six cases seen from the Houston area between July, 1943, and December, 1944. Five of these were bilateral, one unilateral. An additional case is reported which has all the earmarks of the syndrome, but which lacks a history of rubella in the mother.

CASE REPORTS

Case 1. Barbara M. was born at full term and of normal weight. The mother had contracted rubella during the first month of pregnancy. The cataracts had been noted at birth. We saw her when she was seven months old.

The eyeballs were much smaller than normal, the pupils were completely

opaque; there was a coarse lateral nystagmus and alternating convergent strabismus. She had a congenital heart lesion and defective hearing. The pupils were equal and reacted promptly to light. They dilated regularly and well with homatropine and paredrine, showing a clear ring of tissue around the opaque center. The right lens was needled by Ziegler's method when the child was 11 months of age and the left one a few weeks later. There remains a membrane across each pupil and there is a high degree of alternating convergent strabismus and severe nystagmus. The mother writes that the baby's vision is improving, that she picks up small objects and notes colors.

Case 2. Stephanie S., aged three weeks, was examined on December 6, 1943. The child was born at full term and weighed seven pounds. The mother had had German measles during the second month of pregnancy. Both eyeballs were microphthalmic; the lenses in the pupillary area were completely opaque. The pupils dilated equally and well, showing an opaque center with some clear lens substance in the periphery. The opacity seemed to come farther forward in the left eye. This was a "blue baby," probably from absence of the interventricular septum. It was thought best to give the baby time to gather strength before operating. On September 21st a needling was performed on the right eye. This left a thin membrane, which was incised on November 6, 1944, at the same time that the lens of the left eye was needled. The tiny opaque nucleus came into the anterior chamber and took several weeks to become ab-

*From the Department of Ophthalmology, Medical College, Baylor University, Houston, Texas.

sorbed. The child now has clear pupils, with alternating convergent strabismus.

Case 3. George F. was seen on December 20, 1943, when he was three months old. He was born at seven months, was a twin, the other baby having been still-born. He weighed $3\frac{1}{2}$ pounds. The mother had had German measles in the first month of pregnancy. The child was poorly developed and had a congenital heart lesion. At 19 months he weighed $18\frac{1}{2}$ pounds, did not crawl nor stand alone, and threw his head backward in a manner characteristic of these infants. The pupil of the left eye was opaque at birth, that of the right not completely so, but at the examination both seemed the same. There was a fine lateral nystagmus. The eyeballs were considerably smaller than normal. The pupils dilated fairly well. There were no posterior synechiae. A small ring of clear cortex surrounded the opaque centers. On July 24, 1944, the lens of the left eye was needled. The lens material was not absorbed well, and a rather thick membrane remained which became vascularized from large vessels in the iris. The lens of the right eye was needled on September 7th and the nucleus was broken up with the knife. The membrane and iris of the left eye were incised at the same operation. The baby now has a clear black pupil in the right eye, and an elongated slit in the left.

Case 4. Carolyn M. was brought for consultation March 21, 1944, when she was three months old. She was a full-term baby and weighed 4 lbs., 6 oz. at birth. She was the fourth child, the other children all having normal eyes. The mother had had rubella early in the third month of pregnancy. The baby had a congenital heart lesion and poorly developed musculature. Both eyes were very small, and the

pupils were completely obstructed by opaque lenses. There was a coarse lateral nystagmus. The pupils dilated poorly but there was no synechiae. A small rim of clear lens material surrounded the opacities. On October 21st the lens of the right eye was needled and the nucleus broken up with the knife. On December 13th the same operation was performed on the left eye. The baby now has clear black pupils, but in the left eye the iris is adherent to the puncture wound. At 16 months the child can sit alone but cannot stand nor walk. She seems apathetic and doubtless has subnormal mentality.

Case 5. Judith M. was brought for consultation on May 15, 1944, at five months of age. She was an 8-months baby and weighed 5 pounds at birth. She had gained 6 pounds since birth and looked well nourished. She was the second child, the first being normal. The mother had German measles in the first month of pregnancy. The child had a congenital heart lesion and became somewhat blue on exertion. There was a slight lateral nystagmus. The eyes were somewhat smaller than normal. The pupillary area of the right eye was completely covered by the lens opacity; that of the left was less dense. There was a rim of clear lens material in each periphery. The pupils did not dilate well with any mydriatic. Needling was performed on the right eye on September 8th. The lens substance was absorbed slowly, leaving a white spot in the center of a thin membrane. On November 21st the membrane was incised and at the same operation the lens of the left eye was needled and the nucleus macerated. The lens material in the left eye was absorbed poorly, so it was attacked again on January 5, 1945. By January 25th there was a clear central opening surrounded by unabsorbed lens substance. At 17 months the child does not sit nor

stand alone. It has intermittent convergent strabismus and a fine lateral nystagmus.

Case 6. Sammie L., aged nine months, was examined on September 11, 1944. There was a cataract in the left eye completely covering the pupillary area. With the pupil dilated it was found that only the central area was involved, with a clear ring about it. The eye was definitely smaller than the other. There was no nystagmus. The lens of the right eye was clear. The mother had had German measles early in the second month of pregnancy. The child was born at term and weighed $5\frac{1}{4}$ pounds. He was a difficult feeding problem and had a behavior pattern similar to that of the babies with bilateral cataracts—such as dropping his head backward and pressing on the eye with the hands. We did not operate upon this child.

Case 7. John W. P., Jr., was brought to us for consultation on December 12, 1944, when he was one year old. He was undernourished, poorly developed, and had a congenital heart lesion. The eyes were about normal in size; both pupillary areas were obstructed by opaque lenses. The pupils dilated poorly but some clear lens materials surrounded the central areas. Both ears were discharging. The mother denied having had any illness during pregnancy that could be called German measles. The baby was referred to the University of Texas Clinic for operation.

SUMMARY

In reporting these cases we are presenting nothing new, but there has been very little published about it in the American literature and it seems that the appearance of six cases of congenital cataracts in infants whose mothers had rubella during pregnancy, in one office, within a year, makes it a serious enough

problem to merit more discussion. Throughout the Gulf Coast area of Texas an epidemic of German measles occurred in 1942 and 1943. The cause of this disease is unknown but it is quite infectious. Affected persons were not very sick with it and in some cases it was probably so mild as to make little impression. That is possibly what happened in case 7. The epidemic was characterized by pharyngitis, cervical adenopathy, mild fever, and a papular rash which began on the face and spread downward.

There are several peculiar features about this syndrome that in the light of our present knowledge defy explanation. The deformities following German measles in the mother are too much a part of the picture to pass it off as a coincidence. It is true that we have never thought to question the mothers of children with congenital cataracts concerning this kind of infection until it was called to our attention. It seems likely that through the placenta some toxin reaches the embryo that is specific in arresting the development of certain organs, particularly the eyes, the heart, the auditory apparatus, and perhaps the central nervous system. The Australian investigators found that if the mother contracted German measles within the first two months of pregnancy the chances of the child being affected were 100 percent; whereas if the infection appeared in the third month they were 50 percent. Presumably from there on the percentage drops rapidly. This of course brings up the question of the justification for therapeutic abortion when the postulates for 100-percent affection of the child have been fulfilled. Personally we believe that it is better that these miserable little creatures be not brought to birth. Convalescent serum has been used on mothers, but so far as we know no reliable statistics as to its efficacy are available.

These cataracts differ from other congenital cataracts that we have seen. They are usually in microphthalmic eyes, which in itself is bad. The embryonic nucleus is usually alone involved, and may have become so tough and hard that it is difficult to fractionate. In this event absorption is slow. Because of the poorly developed muscles of the iris it is difficult to dilate the pupils with any mydriatic and to keep them dilated after operation. Fortunately, these do not have the characteristics of congenital cataracts caused by intrauterine inflammation as denoted by firm posterior synechiae. We have never seen an eye of this kind successfully operated upon, for each operation is invariably followed by inflammation and fibrosis.

All of our patients were operated upon under ether anesthesia, and no difficulty was encountered. This is contrary to Lawrence Post's experience. He advocates local anesthesia. We encountered no trouble with secondary glaucoma after operation. This may be due to the fact that the lenses were so small that the material turned loose by the knife was not sufficient to swell and close the angle, or for the debris to clog it. As the eye also is small, often commensurate with the size of the lens, another factor may explain it. This is the type of discission in which the posterior capsule as well as the anterior is cut, as advocated by Ziegler years ago. We have had no secondary glaucoma in congenital cataracts since adopting this method.

It is probably wiser to operate upon these infants very soon after birth instead of waiting the 10 or 12 months usually advocated for congenital cataracts. This might prevent the searching movements these eyes develop and when this starts it never disappears. We did not operate as early as this on our patients because of their poor physical condition, but we have decided that the risk should be taken in the future. Glasses should be put on these babies as soon as clear pupils are obtained.

CONCLUSIONS

Seven cases of congenital cataracts are recorded, all of them accompanied by other defects, usually congenital heart lesions, poorly developed musculature, and retarded mentality. Six of these were bilateral, one unilateral. Six of the seven mothers had had German measles in the early months of pregnancy. One mother whose baby had the syndrome gave no such history.

The cataracts are typical in that the embryonic nucleus, which develops soon after the fibers are laid down, is affected.

Five of the patients had both eyes operated upon under ether anesthesia. The through-and-through discission advocated by Ziegler was done. Fair results were obtained in all cases. Secondary glaucoma did not occur.

It is doubtless wiser to operate upon these infants within the first two or three months of life, before nystagmus begins.

HYSTERICAL AMBLYOPIA

ITS DIFFERENTIATION FROM MALINGERING

ELTON R. YASUNA, M.D.
Worcester, Massachusetts

In the Army, Separation Centers have been set up for the final complete physical tests for soldiers about to be discharged or "separated" from the Service. These soldiers are received from various Army hospitals or stations throughout the country and are, for the most part, selected because of physical or mental disabilities of sufficient degree so that no suitable assignment is available for them in Service. The men are sent to the Separation Center nearest their homes; the last station from which they return to civilian life. At the time of the final physical examination definite diagnoses must be made together with a ruling as to whether the condition is or is not in line of duty or aggravated by military service. Records from previous stations or hospitals aid in the final diagnosis and evaluation.

In the Ophthalmology Department of the Separation Center at Fort Snelling, Minnesota, a number of interesting and unusual cases of poor vision were encountered, all of similar pattern. The first of these was not immediately recognized and resulted in an incorrect diagnosis of ocular malingering. From the records that accompanied these individuals it could be deduced that previous examiners also had been uncertain of the condition present, and were in doubt about the diagnoses.

METHOD OF APPROACH

The soldier usually had an uncorrected vision of 20/200 or 20/100 in each eye which lenses did not improve to any appreciable extent. A pinhole in the trial frame placed first before one eye and then before the other gave the same re-

sults; namely, vision about 20/100. Flashlight observation of the lids, conjunctiva, cornea, and pupillary reaction was negative, and ophthalmoscopic examination of lens, vitreous, and fundus also showed no abnormalities. Of those with previous clinical records the examination also had proved to be negative except for poor vision. The records of some of the individuals showed consultation with the psychiatry department for evaluation, and malingering, hysteria, and neurasthenia were considered.

The majority of these soldiers were being discharged with poor vision, although previously upon entering the service they had passed the visual requirements. In all but three cases the vision originally had been adequate for general service, and although the ocular standards for general service have been changed from time to time since January, 1942, corrected vision of at least 20/40 in each eye had been the minimum requirement during most of this period.

After determining the distance vision with either lenses or pinhole spectacles or both, the visual acuity for close work was next determined by use of the Jaeger chart. In this test the results ranged from ability to read Jaeger 1 with ease, to difficulty with reading type one inch in height. The possibility of malingering was again suggested by these results, and this point will be enlarged upon later.

A visual field was then plotted on a tangent screen. In all these cases a markedly restricted field was found, varying between 1 and 25 degrees, with little or no increase in the size of the field as the patient was seated two or three times farther back than the original distance.

This, of course, is the so called "tubular field" characteristic of hysteria. These cases were also seen by the psychiatrists* at the Separation Center who helped in the clinical diagnoses.

After the desired data such as history, distance and close vision, ophthalmoscopic examination, and visual fields had been noted, the subject was taken aside, and in privacy the following line of suggestion was applied. A sympathetic and paternal attitude was assumed. It was explained that his present vision was poor, to which the soldier would usually agree in a sad tone of voice. However, because of this finding and since no immediate cause could be found for this decrease in vision by the present limited examination, it might be necessary to hospitalize him if a recheck did not show any change. The next step was that he should "rest his eyes" for 10 or 15 minutes. This "resting" was done in the dark room. After this, and still in a helpful and encouraging manner, all the tests were repeated, the results of which are reported later.

CASE REPORTS

Incidence. A total of 15 cases of hysterical amblyopia was seen during the examination of the first 1,700 cases at the Separation Center. Only 86 percent (1,462 soldiers) were discharged because of physical or mental defects, the remainder being separated for other reasons such as dependency, essential to the public health, and the like. The frequency should be calculated from the group with these defects, with a resulting incidence of just over 1 percent. However, these are not a random group of servicemen but rather

are selected cases recommended for discharge because of specific reasons. Thus one cannot learn from this report what the frequency is of amblyopia due to hysteria among servicemen in general except to say that it is not rare.

Age. Two thirds of the soldiers were in their twenties, with lower and upper limits of 20 and 39 years of age. The average service man was 27 years old, and the mean age 25.5 years. Since the general group of men in service are between 18 and 45 years old with a predominance of those less than 30, the average and mean ages found in this series correspond with the average age of service men. It cannot be said that hysterical amblyopia is predominantly seen in younger men.

Branch of service. There was no one branch of service to which a predominance of the cases belonged. Five were assigned to the Infantry, two each to the Signal Corps and Medical Department, one each to Ordnance, Combat Engineers, Cavalry, Coast Artillery, and Detachment of Enlisted Men's Lists; one was unassigned. That five cases were from the Infantry was to be expected, since this branch of the Army is by far the largest.

Length of service. In general, the men had been in service between one and three years, with extremes of 10 weeks and four years. Some had served well, and of the four who had been overseas two had been in combat under intense fire. However, during the last 6 to 12 months of their service the records had shown repeated treatments by the medical branch either in clinics or hospitals, with gradually diminishing value to the Service.

Vision. The optimum corrected vision on the initial examination was 20/200 or 20/100 in two thirds of the cases (table 1). This vision was obtained by glasses or pinhole spectacles, whichever gave the better results. It was both interesting and

* Marvin Sukov, Comdr. (MC), U.S.N. and John Miller, Capt. (MC), A.U.S. of the Psychiatry Department were most helpful in evaluating these cases and providing suggestions in the work-up.

characteristic that these men would read about 20/100 to 20/200, usually O.U., and not 20/400 or 20/800 or 20/50. Typically the soldier wearing his correction and using binocular vision would say, "I can only see the big letter" (20/200), or possibly read the next line (20/100), with great effort and long pauses between letters. Urging on the part of of examiner to have another line read would be

quent blinking, "resting of the eyes" by closing them for a few minutes, rubbing of the lids, and a pained expression were characteristic of the individuals. It would often take 10 or 15 minutes for the soldier to read from the 20/200 line to the lowest possible, with occasional rests during the test. Therefore, in the later cases reading was begun on the 20/40 line with progression to the smaller type.

Figs. 1, 2, 3 (Yasuna). Visual fields in cases of hysterical amblyopia.

Fig. 1, case 3. Soldier 33 years old, 38 months in service; overseas 27 months. Claims "weak eyes" since 1930, becoming worse in service. Vision: O.D. 20/100; O.S. 20/200, with 10-degree tubular fields regardless of size of test object (4 mm. at 1 M. and 3 M.; same size field with 4" object). Jaeger 1 read with ease. After suggestion, vision was 20/30 in each eye but the fields remained unchanged.

Fig. 2, Case 9. Soldier aged 31 years, 49 months in service; 32 months overseas. Claims "weak eyes" after shell explosion on Anzio Beachhead in November, 1943. Vision: O.D. 20/100; O.S. 20/70, with 15-degree tubular fields (4 mm. white test object with no change at 1 and 3 M.). After suggestion, vision was: O.D. 20/40; O.S. 20/30—; fields unchanged.

Fig. 3, Case 10. Soldier aged 37 years, 10 months in service; not overseas. Claims a poor right eye since childhood. Vision: O.D. 20/70; O.S. 20/20. Right field 2 degrees, left field 4 degrees (4 mm. test object at 1 and 3 M.; same size field with large sheet of paper). After suggestion, vision was O.D. 20/30; O.S. 20/20, while fields increased to 30 degrees in each eye and were not tubular.

of no avail. Most wore glasses, with refractive errors of all types represented. In only one was the ametropia of high degree, this being in the case of a hyperopia of seven diopters.

After suggestion, the corrected vision was improved to 20/30 or 20/40, and in some instances to 20/20. Here again the reading was slow and deliberate with long pauses between letters. This delay and great effort in reading frequently occurred whether the soldier was reading the 20/100 line or the 20/30 line. Fre-

Visual fields. Visual fields were plotted on the tangent screen rather than on the perimeter.* In all except one (case 6) the fields were tubular in character; in the one exception, although the fields enlarged as the distance from the screen was increased, the enlargement was by no means proportional. In this case the fields were also found to be considerably re-

* One of the black painted walls of the dark room was used as the tangent screen. This served well since it was possible to obtain privacy and quiet, both of which were desirable in testing these men.

duced. The usual plotted field, when a 4-mm. white test object at one meter was used, was found to be between 8 and 15 degrees in 13 (86 percent) cases. Use of the same test object at three meters gave identical fields (figs. 1 and 2). In the remaining two cases, very small fields between 2 and 4 degrees were obtained with no enlargement at three meters (fig. 3).

In addition to the tubular characteristic, certain peculiarities concerning the fields in these individuals are worthy of mention. First, the plotted fields were found to be uniformly round rather than with the normal increase temporally and temporo-inferiorly (fig. 1). If a 10- or 15-degree field was obtained, the isopter distance from the fixation point was as regular as though drawn by compass, and this finding persisted regardless of the distance from the fixation point. After a few points were plotted, all other points fell about the same distance from the center, and the examiner could usually surmise fairly accurately when the patient was going to see the test object. There was no tendency to concentric decrease of the fields on prolonged examination, a finding usually referred to as spiral fields. Although some books on perimetry mention this characteristic as observed in hysteria, Peter¹ and Traquair² carefully explain that spiral fields are seen in neurasthenia and not in hysteria. This observation has been constant in the cases being reported and helped establish these individuals as true hysterics and not as neurasthenics.

Secondly, little or no change occurred in the size of the field as the size of the test object was increased. In many of the cases the test object was increased from 4 mm. to a square of white paper four inches on edge, but the visual fields were unaltered. In cases 10 and 14 (table 1) where a 2- to 4-degree field was present,

this extreme constriction persisted even when a sheet of white typewriter paper was used, a rather dramatic observation. This finding shows the steepness of the field margins that is marked in hysteria. Organic lesions rarely show this. In the small group reported here, this steepness of the field margins has been consistent and deserves further emphasis in describing the typical field changes in hysteria.

Visual fields after suggestion. In all but three of the cases the visual fields remained about the same after suggestion. In the three who presented alterations the changes indicated an increase in the size of the field to about 30 or 40 degrees; thus the field was larger than originally but still constricted. The circular contour and steep edges remained.

Near vision. In about half of the cases the near-vision, results as tested with the Jaeger chart did not correlate with the distance vision. In six instances (40 percent), Jaeger 1 was read, usually with ease, although distance vision was 20/100 or 20/200. Apparently the patients had no insight into the inconsistency of this finding and once more malingering came to mind.

DISCUSSION

An interesting group of 15 cases of hysterical amblyopia was reported by Halpern³ while stationed at a preëmbarkation camp. In these instances the amblyopia developed acutely while the individuals were awaiting overseas duty, and all improved on hospitalization without any specific therapy. The vision was usually 20/100 or 20/200, with extremes of 20/60 and 10/400. The majority gave no previous ocular history. The fields were usually tubular and below 20 degrees, but in two cases no field changes were found. Pupillary and corneal reflexes were usually normal, and no marked refractive errors were present.

Mahoney and Linhart⁴ observed 13

TABLE 1
EYE FINDINGS IN 15 CASES OF HYSTERICAL AMBLYOPIA

Case	Age years	Maximum Corrected Vision		Visual Fields	Other Findings
		First Examination	After Suggestion		
1	36	O.D. 20/70 O.S. 20/70	O.D. 20/30 O.S. 20/30	15', tubular	None
2	24	O.D. 20/100 O.S. 20/100	O.D. 20/40 O.S. 20/40	8', tubular	Myopia (3D)
3	33	O.D. 20/100 O.S. 20/100	O.D. 20/30 O.S. 20/30	10', tubular	Myopia (2D); Jaeger 1 read easily
4	21	O.D. fingers O.S. 20/200	O.D. fingers O.S. 20/20	8', tubular	Convergent strabismus right, with amblyopia; Jaeger 1 read easily
5	39	O.D. 20/100 O.S. 20/100	O.D. 20/30 O.S. 20/30	15', tubular	Myopia (1D); Jaeger 1 read easily
6	21	O.D. 20/100 O.S. 20/200	O.D. 20/30 O.S. 20/50	20', not tubular, but not proportionate for distance	Alternating esotropia; Jaeger 1 read easily
7	21	O.D. 20/100 O.S. 20/200	O.D. 20/30 O.S. 20/50	10', tubular	Compound hyperopic astigmatism, moderate
8	20	O.D. 20/200 O.S. 20/200	O.S. 20/30 O.S. 20/30	10', tubular	Fields not tubular after suggestion
9	31	O.D. 20/100 O.S. 20/70	O.D. 20/40 O.S. 20/30	15', tubular	None
10	37	O.D. 20/70 O.S. 20/20	O.D. 20/30 O.S. 20/20	2', tubular (right); 4', tubular (left)	Myopia (2D); 30' fields after suggestion
11	22	O.D. 20/100 O.S. 20/100	O.D. 20/40 O.S. 20/40	10', tubular	Hyperopia (7D); Jaeger 1 read with effort
12	26	O.D. 20/70 O.S. Light perception	O.D. 20/20 O.S. Light perception	10', tubular	High mixed astigmatism, O.S., with amblyopia
13	26	O.D. 20/100 O.S. 20/100	O.D. 20/100 O.S. 20/100	8', tubular	Bilateral mixed astigmatism, moderate
14	25	O.D. 20/100 O.S. 20/200	O.D. 20/30 O.S. 20/40	2', tubular	Jaeger 1 read easily
15	25	O.D. 20/30 O.S. Light perception	O.D. 20/30 O.S. Light perception	10', tubular	Divergent strabismus, left, with amblyopia; Jaeger 1 read easily

instances of this condition among servicemen. The amblyopia was bilateral in all but one instance. These cases were more chronic than in Halpern's series but of milder degree, with corrected vision usually between 20/40 and 20/100. Fields were typical. In this group life-long histories of poor vision were the rule, and

most were emotionally immature, with poor intellectual endowments. These soldiers were similar to the ones reported in this paper.

Nature of hysterical amblyopia. Moersch⁵ has succinctly described this as "that convenient curtain that shuts out unpleasant experiences from visual mem-

ory." In 1930 Spaeth⁶ presented an excellent review of hysterical amblyopia and its background. He explained that the hysterical make-up from the standpoint of personality defects was manifested by a poor synthesis of the personality. This made it possible for certain groups of ideas to drop from an effective association with the main portions of the personality and to occupy a region first called and explained by Janet⁷ as the "subconscious."

Hysterical anxiety with conversion phenomena is the manifestation of a higher psychologic mechanism, and generally represents an unconscious wish. When situations of extreme difficulty arise there are but two alternatives—fight or flight. However, according to Janet's theory, an hysterically constituted person may develop a compromise situation between instinctive cravings and what external reality permits. He does this by taking on some bodily incapacity as a legitimate excuse for abandoning the struggle and thereby squaring his own conscience. It is thus a flight from reality or a "flight into sickness." Such a reaction represents a partial break in mental control; that is, a shutting off of recognition by the psyche of some organic function. In hysterical amblyopia this would be the inability to see, although the eyes anatomically are capable of vision.

The hysterical conduct may be infantile and ineffectual but it represents that particular person's most efficient way of meeting and adjusting to a situation. As Freud⁸ has shown, repression is the fundamental factor and the basis of hysterical manifestations. These individuals suffer from reminiscences, and their symptoms are the remnants of certain experiences. They have driven these experiences out of consciousness and out of memory, in this way saving themselves a great amount of psychic pain. However, they still exist in the subconscious only wait-

ing for their chance to become active and finally succeed in sending into consciousness a distinct but unrecognizable form of the repressed idea—which is the symptom.

Wechsler⁹ in his "Textbook of clinical neurology" explains that there is hardly a sign or symptom of organic disease which hysteria cannot simulate. It is the most protean disease in the whole domain of medicine.

Monosymptomatic hysteria is not at all uncommon, but the greatest number of cases present a variety of manifestations.

In this group, the predominant symptom was poor vision, but on going further into the history the psychiatrists uncovered other complaints and findings which fitted into the picture of hysteria. The majority, therefore, were not monosymptomatic but presented multiple symptoms.

For convenience, the hysterical amblyopias have been divided into three broad groups: 1. Acute—the amblyopia develops suddenly, and the course is usually short. 2. Chronic—the condition has existed for some considerable time, does not have a definite time of onset, and the course may be complex. 3. Mixed—in addition to hysterical amblyopia, other elements of psychoneurosis or neurasthenia are also present and frequently are the more obvious factors in the individual.

The more common ocular findings in hysteria as described by Head¹⁰ are amblyopia, photophobia, corneal anesthesia, ptosis, blepharospasm, diplopia, lacrimation, and intermittent attacks of blindness. Most of the cases in this report belonged to either the chronic or mixed category, and the outstanding finding was the amblyopia.

What is accomplished by suggestion?
It is generally agreed that suggestion is the most important factor in the treatment of hysteria,^{7, 8, 9, 11} and this holds true in

the case of hysterical amblyopia as well. Earlier in the paper the method of suggestion used in these cases was outlined briefly. It was felt that these individuals could not adjust to their setup in service, although no severe difficulty had been encountered previously in civilian life. Basically the line of suggestion employed emphasized that because of the present poor vision they could not be discharged or "separated" from the Army. Hope was maintained by suggesting another examination after "resting the eyes."

The hysterical amblyopia probably had developed because the individual could not get along in service although he did not realize or admit this in his consciousness. Now the defective vision, which was the soldier's method of adjustment to the Army, however inadequate, was resulting in his remaining in service. Obviously the symptom (amblyopia) was no longer serving the desired purpose, and so vision was regained.

The suggestion was brief and the explanation of the resulting mental process crude but probably near the truth in most instances. The belief that the underlying factor in these cases of hysterical amblyopia was the inability of the soldier to adapt to the Army was assumed, and may not have been the cause at all in some of these individuals. Thus in case 13 no improvement in vision was obtained after suggestion, so that perhaps the Army was not his difficulty and discharge was not the remedy.

Since hysterical amblyopia is rare in civilian life,* especially in males, whereas it is relatively frequent among those in service, it is probable that factors in Army life are the important cause of hysteria.

Although the improvement in vision obtained in this series after suggestion was probably only transient and by no means

a cure, this finding aided in the diagnosis of the condition. It also helped in establishing the fact that the individual was capable of good vision and removed the element of doubt and error which always should be in the mind of the examiner in making the diagnosis of a functional condition.

Differentiation between hysterical amblyopia and malingering. Moersch⁵ emphasizes the point that although "hysteria is used frequently in place of malingering, the two terms are not at all synonymous." However, the diagnosis of malingering is frequently difficult and in service becomes an especially inviting pitfall. As stated by Shelton,¹² "the examination of the malingerer becomes a battle of wits, and he may make you feel that your years of special training were spent in a kindergarten."

Fundamentally, the hysterical person is largely if not wholly unconscious of the unreality of his symptoms. He deceives himself and others without design or malice, often without demonstrable motive, although this exists. The malingerer, on the other hand, deceives willfully and knowingly; he realizes the falseness of his complaints and findings. Both the malingerer and the hysteric are frequently of poor emotional and psychiatric quality, however, and the examiner may be hard put to distinguish the two.

The malingerer may have symptoms of hysteria, and hysterics may simulate. Trapping a patient with amblyopia into seeing is not proof of malingering. Trickery may suddenly arouse attention in hysteria, and therewith sensation. The differentiation between the two conditions can be made, however, and is of the utmost importance, since the treatment and handling of such patients depends upon the diagnosis. Several factors will aid in differentiation and when assembled will lead to the correct diagnosis:

* Wechsler states that he has rarely encountered hysterical amblyopia in civilian practice.

1. The hysteric is indifferent and nonchalant in regard to his ailments and does not seem particularly upset about the amblyopia. The malingerer, conversely, is worried about his condition; frequently, too much so.

2. In hysterical amblyopia the subject has no difficulty in getting about and rarely bumps into objects or hurts himself, even though his fields may be markedly constricted. The malingerer, however, is "blinder than blind," often completely helpless. Eggers's¹³ description is characteristic of their "sometimes affecting difficulty in walking about in dim illumination although the peripheral fields were normal. Invariably they overplayed their part."

3. While the hysteric revels in examination, no matter how long or how often repeated, the malingerer loathes this, is sulky, resentful, and not coöperative.

4. In hysteria the amblyopia is usually bilateral, in the malingerer more frequently unilateral.

5. Varying degrees of visual acuity obtained through "trick tests" is uncommon in hysteria, whereas frequent and very suggestive in malingering. Again, though, these so-called malingering tests should not be the sole basis for differentiation, since hysteria will give positive results in some instances. The person with true hysteria may respond to these tests in the same manner as the simulator.

6. The results of the peripheral-field examination are outstanding and characteristic in hysteria. The tubular, concentric field with steep borders, proved by constancy with varying-sized test objects, and often showing a reversal of color fields, are usually diagnostic of hysteria. With these findings the burden of proof rests on the examiner to disprove hysterical amblyopia and to diagnose malingering. Few malingerers can deceive intelligently on fields.

Of the 15 cases of hysterical amblyopia reported here, none was diagnosed as such before referral to the Separation Center. This was more probably due to the omission of perimetric examination than to any other single factor. In several instances, before the correct diagnosis was made, the possibility of malingering was strongly present in the mind of the examiner, especially when "trick test" results such as reading Jaeger 1 with 20/200 corrected distance vision were obtained. It was only after the complete data were assembled that the tentative impression of malingering could be shown to be false. There have been ocular malingerers at the Separation Center, but these have been rare compared with the occurrence of hysterical amblyopia.

It may be said that a tentative diagnosis of hysterical amblyopia should be strongly considered in an individual with bilateral amblyopia and no organic findings who previously has had good vision.

Evaluation of disability. These soldiers with hysterical amblyopia have filed claims with the Veterans' Administration, and the problem arises of evaluating the amount of existing disability. I do not believe any of this group were familiar with disability ratings. Many would not have filed claims except that they were urged to do so because of possible disability.

In the United States Veterans' Administration "Schedule for disabilities," March, 1933, maximum vision of 20/200 in each eye (such as in case 8) is entitled to 60 percent disability; 20/200 in one eye and 20/100 in the other to 50 percent disability (cases 2, 3, 5, 11, 13), and so forth, depending on the vision. No mention is made as to whether the cause of the poor vision is organic or functional as long as certain requirements as to the methods of testing are fulfilled.

On page 40 in the "Schedule for disabilities" certain disability ratings are

listed for diminution in the peripheral visual fields. Thus, bilateral concentric contraction of the fields to 10 to 30 degrees is judged to be a 40-percent disability, whereas contraction to less than 10 degrees in each eye is ruled a 100-percent disability. However, this table has a note which wisely states that "demonstrable organic pathology commensurate with functional loss will be required," and that "ratings for functional contraction or field losses will not exceed ratings for hysteria."

Reference to disability compensation for hysteria groups this condition with other types of psychoneurosis. Five groups are distinguished, depending upon the amount of subjective and objective symptomatology and the amount of social and industrial incapacity. The determination of ratings is dependent upon difficulty in the veteran's economic adjustment; that is, impairment of earning capacity. The type of disorder, severity, persistence, and continuity of the symptoms are also considered.* Disability ratings for

the designated five classes of psychoneurosis are 0 percent, 10 percent, 30 percent, 50 percent, and 80 percent.

Since the ocular findings in these cases are only a manifestation of hysteria and not due to any demonstrable pathologic process in the eyes, the disability ratings should be on the basis of the severity of the hysteria.

CONCLUSIONS

1. Fifteen cases of hysterical amblyopia were observed at the Separation Center at Fort Snelling, Minnesota. This was an incidence of 1.03 percent among those discharged for organic or mental disability.

2. The testing of peripheral visual fields was the most important aid in the attempt to arrive at the diagnosis.

3. Differentiation between hysterical amblyopia and malingering is usually possible and should be made, since the treatment and handling of the patient is dependent on the correct diagnosis.

4. Disability ratings in hysterical amblyopia should be based on the severity of the hysteria and not on the amount of visual or field loss.

NOTES, CASES, INSTRUMENTS

ACCESSORY LACRIMAL GLAND ON THE CORNEA

LAWRENCE R. DAME, MAJOR (M.C.)
A.U.S.*

The occurrence in man of a corneal tumor composed solely of glandular tissue entirely analogous to that of the lacrimal gland has not, so far as is known, been previously reported in the literature. Under the circumstances the findings in such a case, recently encountered, are deemed worthy of record.

A private, U. S. Army, colored, aged 28 years, was admitted to a General Hospital with the complaint of "poor sight

The blood, urine, and spinal-fluid examinations and X-ray studies of the orbit and skull were normal. The stool examination revealed mild ankylostomiasis.

The eyes were normal except as noted. The right eye presented (figs. 1, 2) a pink, nonbleeding, soft tumor, 8 by 8.5 by 3 mm., of which 2.5 mm. extended over the bulbar conjunctiva, centering in the 7-o'clock position and 6 mm. over the cornea. The entire mass was covered with glistening, nonvascularized epithelium, and was firmly adherent to the cornea. Two small arterial loops, with accompanying venous drainage, were present at the 6:30- and 7:30-o'clock positions, issu-

due to the lump on my right eye." This "lump" had first been noticed in 1928, when he was 13 years old, at which time it was concealed by the lower lid. It had been completely asymptomatic until the past five years, when a slight but progressive impairment of vision had developed. Six months before this hospital admission minor "tear-gas" stimulation had occurred, which he believed had resulted in a mild residual excess lacrimation of the right eye.

The physical examination, other than of the eyes, was negative for any evidences of hereditary, developmental, or acquired changes of a pathologic nature.

* Chief of EENT Section, Surgical Service, General Hospital, U. S. Army.

ing from the bulbar conjunctiva. Superior and parallel to the upper edge of the tumor, and separated from it by 1 mm. of clear cornea, was an arcuate corneal opacity, 1 by 8 mm. in size, resembling arcus senilis, with incorporated pigment which appeared to consist of melanin granules. The cornea measured 13 mm. horizontally and 13.5 mm. vertically. The pupil of the right eye measured 6 mm., that of the left 5 mm., becoming 4 mm. and 3 mm., respectively, on stimulation with a flashlight. The vision was: O.D. 20/200 and J8 improved to 20/70 and J5 by a +.50D. sph. \approx -2.00D. cyl. ax. 85°; O.S. 20/50 and J3 improved to 20/30 and J2 by a -1.00D. sph. \approx -.50D. cyl. ax. 90° (full homatropine cy-

cloplegia). Color confusion in the right eye was present to both Ishihara plates and colored yarns. The visual field was contracted (3/330/wh/9 C. P.) to an irregular 30-degree field. The left eye was normal except for an equal amount of

ture (figs. 3, 4, 5) resembling normal lacrimal tissue.

The *pathologic report* of the tissue (Major J. H. Bragdon) was as follows: "The specimen consists of a small soft fragment of grey-pink tissue 4 by 2 by 2

Fig. 5 (Dame). High-power magnification of racemose structure and duct of accessory lacrimal gland on cornea. (Museum and Medical Arts Service, Neg. D4317, U. S. Army Medical Museum.)

megalocornea, the refractive error as noted, and a 15-degree visual-field contraction.

The tumor was removed without incident by scissor dissection under procain anesthesia. Microscopic examination revealed 80 percent of the tumor to be of normal-appearing tubulo-acinous struc-

ture, one surface of which appears to be epithelized.

"Microscopic section shows well-formed acini of what is apparently a functioning lacrimal gland. In some sections the excretory duct is seen. The gland is surrounded by a loose connective tissue, which, in turn, is covered by stratified

squamous epithelium. There is no evidence of inflammation or of tumor. *Diagnosis:* Ectopic lacrimal gland."

Convalescence was uneventful, and the cornea healed well with an opacity (fig. 6). The tear production was 20 mm. for the right and 18 mm. for the left eye during a five-minute period, on red litmus-paper strips. Fluorescein appeared on the floor of each nostril in 10 minutes. The patient was returned to the United States because of poor vision.

The embryologic background for the development of anomalies of the orbit and its contents, including accessory lacrimal glands, has been adequately summarized

elsewhere.^{1, 2} Accessory lacrimal glands have been reported in many intraorbital locations, but this is, so far as is known, the first tubulo-acinous structure involving the cornea.

SUMMARY

The occurrence of a corneal tumor, composed solely of tubulo-acinous glandular tissue entirely analogous to that of the lacrimal gland, is reported and, so far as is known, for the first time. Photographs of the eye and photomicrographs of the tumor structure are included.

HERPES ZOSTER OPHTHALMICUS WITH VARIED COMPLICATIONS

HUGH C. DONAHUE, M.D.
Boston

Although herpes zoster ophthalmicus is a rare disease, the literature contains a voluminous record of its course and of many of the conditions that arise in conjunction with it. Recently, Edgerton* described comprehensively the salient factors of the disease and its complications.

There has recently come under my care, however, a case which, because of its extremely unusual variety of complications, merits report. The sequence of conditions that occurred is as follows: acute herpes zoster ophthalmicus, non-ulcerative keratitis with iritis, complete external ophthalmoplegia with ptosis, ex-

ophthalmos, and finally, several months later, violent iridocyclitis. Such a variegated list of complications involved almost every part of the eyeball with the exception of the optic nerve, and demonstrated how extensively this disease may damage the globe and its adnexa. The globe has been reported as being involved in approximately 50 percent of the cases of herpes zoster ophthalmicus and the cornea in about 33⅓ percent of such cases. In the case to be described, corneal involvement occurred during the second week and manifested itself as a subepithelial group of round punctate gray dots 2 to 3 mm. in diameter and some even larger, which were located near the limbus and extended upward toward the central cornea from the 5- to the 9-o'clock position. The corneal epithelium did not become stained with fluorescein, but several folds in Descemet's membrane were present and the cornea showed diffuse edema. This

* Edgerton, A. E. Arch of Ophth., 1945, v. 34, July, pp. 40-62; August, pp. 114-153.

condition subsided after four weeks' progress of the disease, leaving permanent gray corneal opacities scattered throughout the affected area. Considerable iritis was present during the course of this complication, with sharp pain, and this involvement subsided in conjunction with the keratitis.

During the prodromal and acute vesicular stages of the eruption, there occurred extensive edema of the upper lid and less of the lower lid, with almost complete closure of the eyelids. During the eighth week of the disease, however, this edema had largely disappeared, when suddenly the patient noted diplopia with inability to raise the upper lid. In a few days there occurred gradually increasing proptosis of the eyeball with limitation of motion in all directions of gaze. The Hertel exophthalmometer revealed 5 mm. of exophthalmos. This complication of the disease lasted for eight weeks. Its cause has been ascribed to excitation of the sympathetic fibers of the superior cervical ganglion or to muscle atony when it is accompanied by oculomotor-nerve paralysis. Another explanation attributes the proptosis to extraocular-muscle paralysis due to thrombophlebitis within the muscle tissue. The complication of exophthalmos occurring in the course of herpes zoster ophthalmicus is rather rare and has been recorded only a few times; in my case the exophthalmos and muscle paralysis lasted for eight weeks, with muscle function slowly and gradually returning accompanied by recession of the exophthalmos. The complication of the ocular-muscle paralysis occurring during the course of this disease has been reported in percentages varying from 7 to 24 of all cases; in the case under discussion the oculomotor paralysis occurred during the eighth week of the disease, and a substantial lapse of time took place between its onset and the subsidence of the skin lesions.

However, the literature reveals that muscle paralyses do occur at varying intervals during the course of the disease; some investigators have reported paralysis occurring even prior to the cutaneous eruption. In my case, the 3d, 4th, and 6th cranial nerves were involved, and the return of function to the affected muscles was a slow procedure involving 2 to 3 months' time; the muscle abnormality definitely outlasted the exophthalmos, and there was quite definite partial external ophthalmoplegia and ptosis when the exophthalmos had completely receded. This residual paresis completely disappeared within an additional month and ocular motility was then normal, although elevation of the upper lid was somewhat less than normal. The manner in which the ocular-muscle paresis occurs has been attributed to extension of the infectious process to the motor branches of the nerve as it passes into the superior orbital fissure; other theories have attributed the process to an involvement of an associated basal meningitis with nuclear lesions and resultant muscle dysfunction. As previously stated, according to a third theory such muscle paresis results from intramuscular hemorrhages following a thrombophlebitis. These ideas seem to be somewhat in the realm of conjecture, especially in the absence of positive spinal-fluid findings, but in a few cases spinal-fluid examination has revealed a lymphocytosis and occasionally a leucocytosis. These findings would corroborate the extension of the disease to the meninges. From an anatomic and pathologic point of view it would seem that a "spilling over" of the infectious process from sensory to motor branches would be a more logical explanation, in as much as the first branch of the 5th nerve sends out sensory ramifications to all the motor nerves of the eye before it enters the orbit. It is usual for the muscle paralysis to

clear up completely, although, as has been stated, the required length of time varies greatly.

One of the most interesting phases of the case under discussion was the appearance of an extremely severe iridocyclitis nine months following the onset of the disease and following a period of three months during which the patient had been symptom free with the exception of an occasional attack of neuralgia over the affected scalp area. During the early weeks of the disease the iris had shown signs of congestion with one stromal hemorrhage, but this condition subsided following the healing of the keratitis; then, at a time when the patient was apparently well on the way to recovery, there suddenly occurred severe pain, photophobia, and blurring of vision with descemetitis and vitreous opacities. This sequence has been reported previously, but it is relatively rare as such a late complication. The usual symptoms of iridocyclitis were magnified to such a degree together with the appearance of an hypopyon 2 mm. in depth that hospitalization was again required and three weeks of intensive care were necessary before relief was obtained. Atrophy of the iris of moderate degree resulted together with a slight amount of enophthalmos. Two months following the onset of this complication the eye was again quiet and has remained so up to this date (14 months following the onset of the disease). After such a series of complications involving so many parts of the eye, the vision was, of course, substantially impaired, owing to corneal opacities and global shrinkage.

This course of events exemplifies the manner in which this disease may affect an apparently healthy person and the extremely severe damage that it may inflict upon the eyeball.

Case report. Mrs. A. D., aged 54 years, a white American housewife, was first

seen 48 hours following the onset of severe pain in and around the right eye. At this time there were moderate edema and redness of both eyelids with very definite ciliary congestion of the eyeball. The cornea was slightly hazy; pupillary reaction was normal, and the media and fundus were normal. The temperature was 99.2°F., pulse 82, respirations 24. The red blood count was 4,900,000; white blood count 9,200. The patient was extremely obese; physical examination was negative. A definite diagnosis could not be made at this time, but the possibilities of herpes zoster ophthalmicus and erysipelas were considered. Symptomatic treatment for the pain was given. The neuralgia became increasingly severe during the next two days, requiring vigorous sedation, and when the patient was next seen, three days later, the typical skin vesicles were present, extending down to the tip of the nose, involving the eyelids and the right half of the scalp but sharply demarcated at mid-line. The diagnosis was obvious, and treatment was instituted to control the symptoms; no convalescent serum was available.

One week following the onset of the disease, the cornea showed subepithelial punctate deposits which were accompanied by diffuse epithelial bedewing. There was no stain with fluorescein at any time. The pupil was widely dilated with atropine, and the corneal involvement lasted for approximately four weeks, gradually subsiding, but the residual opacities remained as previously described.

During the next weeks the neuralgic pains became somewhat less severe, but the globe remained considerably congested, with moderate edema of the eyelids. The eye remained more or less in this condition until the eighth week of the disease, when diplopia was noted by the patient, and there occurred complete external oph-

thalmoplegia accompanied by proptosis of the eyeball, which took place within five days. This condition, which resulted in 5 mm. of exophthalmos, was unchanged during the ensuing month. Following this period some degree of ocular motility was regained. Muscle function gradually increased, and, following a period of eight weeks, ocular motion was again normal, although there was still present a slight amount of exophthalmos with some ptosis of the upper lid. These conditions returned to normal within another two-week period.

The patient now felt much more comfortable and was practically symptom free for a period of three months. However, nine months following the onset of the original symptoms, there suddenly occurred extreme photophobia with tearing and further loss of vision, and there took place a typical attack of violent iridocyclitis. This required hospitalization of the patient, in an attempt to curb these developments with typhoid-vaccine therapy. Following the initial dose of typhoid, however, a severe tachycardia resulted and medical consultants felt that in view of this condition, and the patient's obesity, further typhoid therapy would be inadvisable. Routine treatment with atropine was given, and after four weeks this condition improved greatly. This involvement occurred about 10½ months after the original appearance of herpes zoster ophthalmicus.

The vision in this eye previous to the disease was 20/20 corrected; following this series of complications the corrected vision is 20/100. The eye is now quiet, although there remains some redness and slight edema of both lids, and a somewhat pronounced corneal leukoma extending 2 to 3 mm. upward from the limbus from the 5- to the 9-o'clock position. The skin eruptions have resulted in scarring throughout the affected area. The patient

has an occasional severe neuralgic pain, especially upon exposure to cold, and the eyeball has become somewhat atrophic owing to the severe iridocyclitis.

Such a variety of complications occurring during such an unusually long lapse of time demonstrates very vividly the manner in which this stubborn infectious process may involve most of the important parts of the eye with resultant impairment of their function.

520 Commonwealth Avenue.

A SIMPLE METHOD FOR THE EXACT MEASUREMENT AND PLACEMENT OF RECESSION SUTURES

HENRY G. WINCOR, M.D.
New York

The success or failure of a muscle operation is dependent on the exact amount of resection or recession.

In the accepted technique of applying the calipers to find the scleral point for new insertion, one is faced with the problem of exactly what points are to be considered as the anatomic insertion. One point seems to be well agreed upon; that is, that the medial rectus is inserted 5.5 mm. from the limbus. According to Whitnall, the measurements made by Fuchs (1884) were taken from the largest series of eyes and are most widely accepted.* His figure is also 5.5 mm. While the lines of insertion of the muscles are not perfectly straight, still those of the medial and lateral recti are most nearly so. The line of insertion of the medial rectus is straight, or slightly convex forward.

The recti insert by means of "thin, flat glistening tendons, formed by parallel rectilinear fasciculi of connective tissue, without anastomoses, but weakly united

* Whitnall, S. E., *Anatomy of the human orbit*. Oxford Edition, p. 266.

by transversely placed and easily separable fibres. Some of the fasciculi leave the main layer to be inserted separately as far back as 1 to 5 mm. behind the remainder of the tendon fibres." Consequently, after the muscle is cut from its insertion and the operator looks down on the stump, he is faced with a picture of thinned, indefinitely inserted fasciculi anteriorly, blending intimately with, and almost indistinguishable from, the superficial fascia bulbi and even superficial scleral fibers. Posteriorly, as has been pointed out, the stump ends indefinitely as far back as 5 mm.¹ Of course, the experienced eye surgeon will pick that point which, in his opinion, is the true insertion of the muscle.

The method I wish to suggest is to pick a much more distinct point to start from; namely, the limbus of the cornea. As has been explained, since the distance of insertion of the medial rectus is quite uniformly 5.5 mm. from the limbus, this distance, plus the amount of recession to be done, can be measured from the limbus. It is best to use the exact horizontal meridian of the limbus to measure from, and extend the scleral point of identification straight up and down, and pick points along this line corresponding to the width of the tendon, if one wants to spread the muscles properly. I suggest the 9:00-o'clock position and the drawing of the straight vertical line with the calipers.

To avoid injury to the cornea from the sharp points of the calipers, the points may be filed smooth and round.

Modification of the recession operation.

1. The internal rectus is exposed and picked up on the muscle hook. 2. A single-needle catgut suture is whipped around the upper border of the muscle close to the muscle hook, and the suture is locked to prevent slipping. 3. A similar suture is applied at the lower border. A small suture clip is applied to the ends of each suture.

4. The assistant lifts up the two catgut sutures vertically, putting the tissues on tension. 5. The muscle is severed close to its attachment. 6. While the assistant still holds the two catgut strands, a third catgut suture is whipped around the cut edge of the muscle at its center and locked. 7. A pair of calipers set at 10 mm. is applied to the eye from the corneal limbus to the sclera on the horizontal meridian. This provides absolute measurement for muscle recession. 8. The central catgut suture is now applied to the sclera at the central caliper marking. 9. The upper and lower catgut sutures are applied vertically above and below this central point. 10. The central suture is now tied; the upper and lower sutures are similarly tied. This procedure presents three sutures in line, giving added strength to the muscle attachment. 11. The caliper measurement is absolute and does not vary as it would in measuring ordinarily from the muscle stump. 12. The conjunctiva is sewed with continuous silk.

SUMMARY

1. In order to recess a muscle more accurately, it is suggested that one measure from the limbus rather than from the original muscle insertion, adding the amount of recession desired to the normal anatomic measurements between limbus and original insertion.

2. The recession operation is simplified, eliminating the use of the muscle forceps, which traumatizes the muscle and introduces an error of 1 mm.

1882 Grand Concourse.

A NEW TYPE OF SURGICAL PEG

SIDNEY A. FOX, LT. COL. (MC), A.U.S.
Martinsburg, West Virginia

Those who have done any amount of plastic surgery have been bedeviled at one

time or another by the rubber pegs used to prevent sutures from cutting through tissues. Especially in these days it is hard to get the proper type of rubber. Often the pegs dig into the tissues and macerate the skin. Passing sutures through a tiny square of rubber is, moreover, a nuisance, is time consuming, and requires the help of an assistant.

After some experimenting with various methods and materials, the following technique was evolved which has proved very satisfactory:

A rectangle of oiled silk, measuring $2\frac{1}{4}$ by 4 inches, is carefully folded into three thicknesses along its length, giving a triple fold of oiled silk measuring $\frac{3}{4}$ by 4 inches. It is then stitched on a sewing machine along the border which does not have the free edge. This stitching is placed one-fourth inch from the edge. It is kept in 70-percent alcohol until ready for use.

When needed, the needles are passed through the stitched edge easily and rapidly and a peg of any desired size is cut

Fig. 1 (Fox). New type of surgical peg.

from the whole piece (fig. 1). The same can be done after the needles have been passed through tissues. One such piece of oiled silk suffices for 12 to 16 pegs, depending on the size desired. These pegs are soft enough so that they do not macerate the skin and sufficiently firm to prevent cutting the tissues.

Newton D. Baker General Hospital.

SOCIETY PROCEEDINGS

EDITED BY DR. DONALD J. LYLE

COLORADO OPHTHALMOLOGICAL SOCIETY

January 20, 1945

DR. GUY HOPKINS, *president*

NEW INJURY, DIPLOPIA FROM OLD INJURY

DR. WILLIAM H. CRISP reported a medico-legal case in which an injury had occurred to the right eye on January 22, 1944. The left ocular adnexa of this patient had been injured 18 years before. The recent injury was caused when the blade of a heater fan came loose and struck the right side of the patient's face, cutting the nose and upper eyelid. The patient, aged 23 years, was a truck driver. Unfortunately, no written record of the case had been made at, or shortly after, the time of the recent injury, but the broad statement was made that, when seen by an ophthalmologist three days after the injury, the right eye showed vitreous opacity, interpreted as due to hemorrhage. When first seen by Dr. Crisp, on June 1, 1944, the right eye was entirely quiet and appeared to be normal with the exception of a dense web of vitreous opacity through which, when the pupil was dilated, many details of the fundus could be seen rather clearly. This eye was almost without refractive error, and had shown vision (under cycloplegia) varying between 20/24 and 20/60, more frequently the latter. The movements of this eye seemed normal. Although there had been a limited cut in the upper eyelid, the eyeball itself showed no appearance attributable to injury except the vitreous web.

Since the recent injury, the patient had complained of double vision. The lower rim of the left orbit showed a marked

displacement, due to fracture of the malar bone, with decided depression of the inner fragment, considerable displacement of the whole orbital floor downward, and a markedly lower position of this eye in relation to the right eye. The left eye had two diopters of mixed astigmatism, correction of which gave vision of only 20/50, although the internal ocular structures seemed normal, and there was no corneal nor scleral scar.

It seemed likely that, for many years, the right eye had been the better eye, and that the left eye had been practically ignored until the injury to the right side of the face. The Maddox-rod test showed from 3.5 to 7 centrads of right hyperphoria and 12 centrads of exophoria. There was crossed diplopia, and the images tilted away from one another at the upper ends. The records obtainable did not altogether exclude the possibility that the web of vitreous opacity might have existed prior to the injury of January 22, 1944. The patient was made more comfortable by wearing the astigmatic correction for the left eye, but he could not drive at night on account of disturbance by headlights. An opinion had been given that the visual loss from the recent injury should be based upon the present corrected vision of the right eye, without regard to the muscular imbalance.

CONGENITAL PTOSIS

DR. R. W. DANIELSON reported on a white child, aged 5 years. This child was first seen at the age of 17 months because of a ptosis of the right upper eyelid since birth. The upper-lid border was just below the center of the pupil. The lid would not elevate on looking up. This child was

seen by Drs. Bane, Sherwood, and Macomber, and surgical intervention was postponed.

On November 28, 1944, a Gifford and Puntenny modification of the Dickey operation was performed. On December 8th, there was a staining area on the cornea and severe entropion, the cilia rubbing on the cornea. A week later when considerable skin was removed from the upper lid, the entropion improved quite perceptibly. Five days after this, an ulceration of the cornea with hypopyon was treated with penicillin and sulfadiazine. On Christmas Day, the patient was much improved, and by December 29th, the hypopyon and ulceration had disappeared, although rather marked opacity remained. On January 1, 1945, the patient was provided with "moisture" glasses and was ordered to wear X-ray protective covering at night. On January 20th, the cornea showed faint stain. The lid elevated with the elevation of the eye and went down with the lowering of the eye. Palpebral fissures were about the same for each eye. It was noted that the right lid did not blink with facility and even seemed able to elevate slightly (a possible associated upturn of the eyes during winking).

INTERSTITIAL KERATITIS

DR. R. W. DANIELSON presented the case of Mr. G. L. The patient, first seen on February 25, 1944, had a history of getting a foreign body in his left eye two days previously. A case of iritis of the left eye was found; the right eye was normal. Vision was: O.D. 20/20-3; O.S. 20/40 (uncorrected). The patient was treated with atropine and typhoid vaccine. On March 1st, he was improved, but just one month later, he was worse, with K. P.'s and corneal opacity beginning. There was no improvement by June 1st. Major Chadwick prescribed 14 hours' treatment in the fever cabinet. On August

9th, when the patient was still unimproved, more typhoid treatments were given, and all suspicious teeth were removed. Sulfonamides were also given. Six weeks later the right eye showed slight circumcorneal redness, but nothing else. Riboflavin and Bicophs were prescribed. The report on October 13th was: right eye—bedewing; K. P.'s and corneal opacity. From November 1st to 5th, 2,000,000 Oxford units of penicillin were administered with no improvement whatsoever. On November 6th, the patient was inoculated with malaria. Two weeks later the malaria reactions started. After six, the reactions terminated spontaneously. The malaria is the only treatment which has seemed to control both the opacification of the cornea and the inflammation. The patient's present condition shows marked opacity of the substantia propria, with K. P.'s and vascularization of each eye. Vision is: O.D. perception of hand movements; O.S. 0.2 (corrected).

Associated facts in this case show that the patient was rejected from the Army because of arthritis. He had secondary syphilis in November, 1936, and had been treated with bismuth and arsenic since then. On August 7, 1944, the Kahn test showed 2+, but was negative on November 2d. The patient also has old pulmonary tuberculosis with strong tuberculin reaction. Both the father and mother had tuberculosis. A brother is supposed to have a corneal opacity of one eye of inflammatory origin. The conclusion was that this patient had interstitial keratitis with anterior uveitis, probably an acquired form, which was possibly aggravated by tuberculous infection.

CHRONIC PEMPHIGUS

DR. W. T. BRINTON reported on Mrs. H., aged 60 years. One-and-a-half years ago her eyelids became red and inflamed

and have been gradually getting worse since that time. She first noticed sore, red spots at the inner canthus of the right eye; soon the other eye became involved. All teeth were removed, and a diagnosis of trench mouth was made. The eyes became increasingly sensitive to light, the lid inflammation progressed, and vision gradually became poorer. In recent months, the patient was troubled with lashes of the lower lids turning in.

In this case, the palpebral and bulbar mucous membranes were markedly involved and showed bands of fibrous connective tissue with shrinkage of mucosa, tending to obliterate the cul-de-sacs. More recently, both corneas have become involved with pannuslike, vascular encroachments from the limbus which interfere with vision. There is secondary iritis, and xerosis is present. There are lesions of the mucous membrane of palate and lips as well as nose. She has been troubled with a vaginitis for two years. In the two years, she has lost 100 pounds in weight.

MONOCULAR MULTIPLE VISION

DR. F. NELSON reported on E. H., a white woman, aged 64 years. She was first seen on December 10, 1943, but had complained about multiple vision for five years. Diagnoses of cataract and glaucoma had been made on different occasions. The right eye had distinct monocular triple vision; the left eye, monocular double vision. There were supranuclear and cortical cataracts in both eyes. Tongue-shaped opacities, protruding from the periphery toward the pupillary area, were apparently causing prismatic apparitions. There were double focusing lenses in both eyes. The discs looked like glaucomatous excavations, but tension was never above 20 mm. Hg (Schiotz). Vision was: O.D. with a $-0.25D.$ sph. $\approx -2.00D.$ cyl. ax. 102° , $5/8$ partly,

and J1; O.S. with a $-0.50D.$ sph. $\approx +2.00D.$ cyl. ax. 175° , $5/8$ partly, and J1, at about 20 cm. distance. Additional plus correction did not improve near vision. A 1-percent pilocarpine solution, instilled once a day, completely eliminated multiple vision in both eyes. Refraction varied considerably, and vision deteriorated slightly during that year.

On October 18, 1944, this patient notified me that her left eye was losing vision rather rapidly in the lower part of the visual field. When she was examined on October 20th, the right eye showed no change, but the left eye had an almost total detachment of the retina, with extensive ragged tears in the upper temporal quadrant, apparently reaching almost into the posterior polar region. The detachment was operated on on October 23d, after temporary dissection of the upper and lower rectus muscles. Complete reattachment was achieved, with normal visual field for white and colored objects, but central vision deteriorated to $5/30$. Double focus in the lens of the left eye became much more pronounced, so that this eye could see about the same with a -5.00 and a $+8.00D.$ sph. The patient reads J2 with the left eye with only astigmatic correction of $+2.00D.$ cyl. ax. 180° . The diagnosis was monocular, multiple vision. Double focus lens, O.U. Refraction difference increasing after retinal detachment, O.S.

SYMPOSIUM ON DIABETES

BIOMICROSCOPY OF THE DIABETIC EYE

DR. MILTON L. BERLINER presented

lantern slides illustrating some of the changes seen in the anterior ocular segment in diabetes by means of the biomicroscope.

HISTOPATHOLOGY OF THE EYE IN DIABETES

DR. LOUISE H. MEEKER presented lantern slides of histologic sections from eyes from diabetics showing various pathologic features.

DIABETIC RETINOPATHY

DR. HERMAN ELWYN said that diabetic retinitis, or retinopathy, is an easily recognizable ophthalmoscopic entity characterized by: (1) small, round, and irregular hemorrhages, situated mainly in the area between the upper and lower temporal vessels and in the region surrounding the optic-nerve head; (2) sharply defined or confluent white exudates in the deeper layers of the retina; and (3) yellowish-white glistening exudates varying in size from a pinpoint to large irregular masses. The small, round, and deep hemorrhages occur only in diabetes and constitute the most characteristic feature of diabetic retinitis. When the small white exudates and the glistening deposits are also seen, the complete picture of diabetic retinitis is present. This characteristic picture does not occur in any other disease.

The ophthalmoscopic picture is at times complicated by changes in the retinal vessels and their consequences, such as: aging, arteriosclerosis, contraction of small vessels, obstruction of a venous branch, and an episodal arteriospastic retinopathy. There is no causal relationship between these changes and those of diabetic retinitis. Some of the severe cases of diabetic retinitis are characterized by large retinal hemorrhages which rupture into the vitreous. A few cases are characterized by the proliferation of newly formed vessels in the retina and the

vitreous which are covered by a connective-tissue layer, different in appearance and genesis from the retinitis proliferans following partial absorption of a hemorrhage in the vitreous.

Hyaline and lipid deposits occur in any tissue that suffers from insufficient nutrition and oxygen supply. Such a condition must be present in the retina in the areas where the exudates are found. The small hemorrhages occur by diapedesis through the walls of the capillaries due to a condition of prestasis. That there is in the retina a chronic prestatic condition with a slowing of the circulation in the capillaries is also shown by the hyaline and lipid deposits, which indicate a disturbed nutrition of the retinal tissue. To explain the prestasis in the retinal precapillaries, with the resulting small hemorrhages, several factors require consideration: The hemorrhages occur in diabetics of all ages and have no relation to the changes in the retinal vessels and their consequences, which occasionally complicate the ophthalmoscopic picture. The hemorrhages occur with severe as well as mild diabetes and are at times discovered before it is known that glycosuria is present. To relate the capillary disturbance to the diabetes, one must consider the mild cases in patients with moderate hyperglycemia, with little secondary nutritional changes, and without the enormous carbohydrate depletion of the liver which results in secondary metabolic changes. Such individuals differ in no manner from nondiabetics save in the lessened ability to regulate the blood-sugar level. It is this prolonged, continuous, moderate-hyperglycemia which stands in some sort of causal relationship to the condition in the capillaries, with the resulting small hemorrhages. This explanation does not solve the whole question of the pathogenesis of diabetic retinopathy. It cannot be stated how the

hyperglycemia produces the retinal capillary peristasis, nor why the hemorrhages are not found in every case of diabetes. Although the large and massive hemorrhages that rupture into the vitreous can be assumed to be due to an aggravated form of prestasis, it is not known why this aggravated form occurs in only a limited number of cases of diabetic retinitis. The newly formed vessels that are found in some cases may possibly be explained by slowing of the circulation in a large number of capillaries at one time and in one area which supplies the stimulus for their formation.

There are no known means of preventing the occurrence of the retinal hemorrhages nor of causing their disappearance once they have occurred. Possibly control of the blood sugar at the normal level of 80-90 or even 100 mg. per cubic centimeter prevents the hemorrhages, but it is not possible to achieve this, and most physicians are quite satisfied when they can keep the blood sugar at about 130-150, which, however, is still a mild hyperglycemia and just the condition responsible for the capillary peristasis and the resulting retinal hemorrhages.

EYE COMPLICATIONS IN DIABETES FROM THE STANDPOINT OF THE INTERNIST

DR. ALBERT A. EPSTEIN said that the incidence of complications in diabetes mellitus is not related to the severity of the disease. Complications occur less frequently in juvenile diabetics than in older patients, although the disease is often more severe in the former. The ocular complications are among the most feared, and retinopathy and cataract give the greatest concern.

There are two views as to the cause of the complications. They may be, specifically, a result of the diabetes, or they may be secondary to antecedent degenerative vascular changes. If they are due to the diabetes directly, proper control of the

diabetes would be expected to prevent their occurrence. In the adequately treated juvenile diabetic, these complications should never develop. O'Brien and Allen found that these ocular changes cleared up with adequate control. Waite and Beetham found that the extension of the life of young diabetic patients permits the ultimate development of vascular sclerosis.

The evolution of the diabetic picture seems to be related to prenatal or hereditary influences; their occurrence in several members of the same family shows their genetic background. Proper control of the diabetes may limit their progression, whereas poor control may speed the maturation of the complications. There is a hereditary taint in every incident befalling the diabetic patient. The usual complications following the administration of insulin are, however, due to hydration; the sugar level of the blood falls rapidly, while that of the vitreous lags; the result is changes in osmotic pressure and in the refraction. The tendency to postoperative bleeding after the use of insulin preoperatively is due to alteration in the blood volume and calls for the judicious use of insulin prior to surgery. It may be that the elevation of the blood sugar is a physiologic adaptation to bring about its utilization; consequently, the lowering of the blood-sugar level by insulin requires care in its use.

The occurrence of local reactions at the region of injection of insulin—tumefaction and atrophy—suggests the possibility that similar toxic changes might take place in susceptible eyes despite their remoteness from the point of injection, as a result of long-continued use of the insulin.

SURGICAL EYE COMPLICATIONS IN DIABETES

DR. SIGMUND A. AGATSTON listed cataract, glaucoma, strabismus, and detach-

ment of the retina as the chief surgical conditions encountered in these patients.

The real gray diabetic cataract is seen only in younger patients. In patients past 60 years of age, the cataract differs in no way from the usual senile cataract and most commonly is nuclear, with some cortical opacities. Indications for surgery are the same as in the ordinary senile cataract. If visibility of the retina is fair or good and vision is disproportionately poor, pathologic change in the fundus or optic nerve, rather than the condition of the lens, is responsible for the loss, and operation is contraindicated. Loss of vision may be caused by iritis, retrobulbar neuritis, advanced diabetic retinitis, hemorrhage into the vitreous, thrombosis of the retinal vein, and detachment of the retina. These pathologic changes may be seen if the lens is transparent, but must be inferred mainly through light projection and visual field when ophthalmoscopy is impossible. The condition of the retina of the other eye is a more important guide than is the blood-sugar determination. Petechial or small retinal hemorrhages and retinal veins of normal character indicate a good surgical risk; whereas engorged veins and large hemorrhages indicate the opposite, and surgery should be delayed or avoided. Operation should be refused in the presence of hemorrhage in the vitreous, retinitis proliferans, or detachment of the retina.

The most frequent postoperative complications are recurrent hemorrhage into the anterior chamber, hemorrhage into the vitreous, detachment of the choroid, thrombosis of the retinal vein, secondary glaucoma, and expulsive hemorrhage.

Primary glaucoma—chronic, simple, or acute—occurs in diabetic subjects, with normal frequency. Surgery may be uncomplicated. Results are influenced by the condition of the retinal and uveal venous systems, as in cataract surgery. During an attack of acute glaucoma, the iris some-

times takes on the appearance of rubeosis, but unless the retinal veins are affected, the operative result is good, frequently even without excessive hemorrhage into the anterior chamber.

Cutting operations to relieve secondary glaucoma following thrombosis of the retinal vein are doomed to failure, necessitating ultimate enucleation. Cyclodialthermy has given relief without enucleation and, aided by a simultaneous paracentesis, has yielded fairly satisfactory results, even with return of light perception. For acute glaucoma occurring with rubeosis of the iris and hemorrhages into the vitreous, only paracentesis through the cornea should be attempted; even this may result in hemorrhage into the anterior chamber, and the prognosis is bad.

While successful intraocular surgery in the presence of a fairly healthy retina is possible with a blood-sugar level even as high as 300 mg. percent, it is best to reduce it by diet or insulin to 200 or less before operating, although it is better not to use insulin on the day of operation.

Squint in diabetic patients is based upon paralysis of the 3d, 4th, or 6th nerve. This generally results in spontaneous recovery after a few weeks to three months, and surgery is not required. Nuclear paralysis of individual muscles does occur, sometimes without recovery. These are probably vascular in origin, but neoplasm, syphilis, and encephalitis must be ruled out.

Ordinary retinal detachment does not occur in diabetics with increased frequency. Secondary detachments, which are frequently found in cases of advanced diabetic retinopathy with retinitis proliferans, are inoperable.

Discussion. Dr. Edward Tolstoi has also noted that eye changes are much more frequent in adults. He has not seen them in children, although he looks for them. In the younger diabetic, he has noted occasional pinpoint hemorrhages,

particularly if the patient is malnourished, and recalls that in the pre-insulin era this lesion was more frequent in children. Their disappearance or relative infrequency now may possibly be attributed to better nutrition rather than to mechanical factors as presented by Dr. Elwyn. There does not appear to be any definite relationship between hyperglycemia and the occurrence of these hemorrhages. A considerable group of diabetics in the second and third decades who had glycosuria and consequently hyperglycemia over a period of years, but who have been free of symptoms of diabetes and have been well nourished, did not reveal the hemorrhages that have been mentioned by Dr. Elwyn as the possible results of hyperglycemia *per se*. Dr. Tolstoi has the impression that so-called diabetic retinitis in the older-age groups represents a resultant of two factors: malnutrition and vascular disease; in the younger patient, malnutrition alone is responsible. When alloxan is injected into animals, the symptoms and signs produced are comparable to diabetes mellitus. Retinal hemorrhages occurred more frequently in those animals given a low-protein diet prior to the production of diabetes. This may be a clue to the nutritive factor.

The preoperative preparation of these patients must be individualized, and one cannot be dogmatic about saying which patients should have insulin.

It is true, as Dr. Epstein pointed out, that there are areas of atrophy where insulin is injected; there are also areas of atrophy near the site of injection. Dr. Epstein's hypothesis that the eye lesions may reflect insulin sensitivity is interesting but requires more supporting evidence.

Dr. A. A. Epstein stated that attempts to normalize the blood sugar in long-standing diabetes by means of insulin are frequently accompanied by untoward developments which occasionally may be

very serious. To support the view that the occurrence of diabetes in more than one member of a family is presumptive evidence of a regressive hereditary taint, even though direct heredity cannot be established, a patient with total diabetes of 27 years' duration was described. She was one of five sisters, four of whom had diabetes, although neither parent showed any sign of the disease. The patient showed no evidence of arteriosclerosis nor eye complications. Eye and vascular complications are not accidental nor the result of the diabetes, but are concomitant with and have the same genetic origin.

Dr. Isadore Givner stated that he had administered hesperidin to a series of 15 patients with diabetes, as a result of a statement by the late Dr. Gifford, at a meeting of the New York Diabetic Association, that vitamin P might be of value in the proliferating type of diabetic retinopathy. After one year, there was no improvement that could be definitely ascribed to this therapy. On the basis of Dam's work, in which he found that vitamin E lowers the blood-cholesterol level, these patients were given this vitamin, again with no definite improvement in the retinopathy.

Dr. Henry Dolger considers diabetic retinopathy to be not an ophthalmologic problem. The internist sees the lesion long before the visual disturbance warrants the attention of an ophthalmologist. There is no question as to the existence of a characteristic retinal picture specific for diabetes. It is seen most strikingly in young adults in whom hypertension and arterial changes do not confuse the findings. The characteristic retinopathy developed in 10 of a series of 43 children followed for over 10 years by Dr. Dolger and Dr. Fischer. During their first 10 years of observation they were optimistic, but, as the period was extended to 15 years and 20 percent of the patients developed varying degrees of inexorable

retinal damage, the optimism was no longer justified. The sequence of events often is: (1) an occasional, small, round hemorrhage is noted near the macula; and (2) with the passage of time, evidence of vascular involvement elsewhere becomes manifest; as, for example, mild progressive hypertension, increasing albuminuria, and X-ray evidence of arterial calcification in the extremities. The eye lesion is apparently the earliest manifestation of some diffuse vascular process; it is not an isolated finding, but is part of the peculiar vascular change in certain types of diabetes. The cholesterol is not significantly altered in these cases. The control of the diabetes and level of the blood sugar are equally irrelevant to the production of the lesion. It is an archaic concept to consider diabetes a simple disturbance of carbohydrate metabolism. Protein and fat metabolism are equally involved in the basic derangement.

Diabetic retinopathy is the most disturbing complication because it occurs in relatively young people and proceeds relentlessly to blindness despite any type of therapeutic approach. The overoptimism often expressed in the literature with regard to juvenile diabetes is dismaying. A report on 73 children having diabetes who were followed for 20 years was concluded with the optimistic claim that the juvenile diabetic can look forward to a normal life and relatively good health. Yet in this report it was almost casually and without anxiety mentioned that retinopathy was found in at least one quarter of the group. The 22 years since the discovery of insulin, and the excellent results of modern diabetic therapy with regard to prolonging life and improving nutrition and resistance, have not witnessed any significant reduction in the inevitable premature arteriosclerosis which continues to frustrate one's efforts.

DR. WARREN S. REESE, *chairman*

TRAUMATIC IRIDODIALYSIS: ITS SURGICAL CORRECTION

DR. A. BARLOW and DR. HERMAN L. WEINER (by invitation) stated that a direct blow on the eye will sometimes cause a detachment of the root of the iris from its ciliary insertion—traumatic iridodialysis. A small separation is of no concern from either a visual or a cosmetic viewpoint. Frequent instillations of atropine and protection from light by dark glasses or bandage may result in a reattachment, according to some authors. However, when the separation is large, there may be monocular diplopia due to a double pupil. Of graver concern in some cases is the unsightly cosmetic effect produced by the the distortion of the normal contour of the iris and pupil.

A six-year-old girl was struck in the left eye with a BB shot. She was admitted to the Mt. Sinai Hospital on April 28, 1943, soon after the accident. The eye was intensely injected, and the anterior chamber was filled with blood. The temporal base of the iris from the 1- to the 6-o'clock position was torn away from its ciliary attachment, which formed a large separation about 5 mm. wide in the horizontal meridian. The pupil was distorted and drawn nasally and up. The fundus could not be seen owing to the hemorrhage in the anterior chamber. The treatment consisted of atropine, antiseptic collyrium, and sterile dressings. As the hyphemia gradually cleared, a fairly good view of the fundus could be obtained through the pupil, but not through the dialysis. Apparently, the rupture had caused a separation of the iris stroma from its underlying pigment layer. The pigment layer

thus prevented a view of the fundus through the dialysis. Later the lens became opaque; a traumatic cataract was the result.

The following operation with its gratifying outcome was devised by P. C. Jameson, and is described by Wiener and Alvis in "Surgery of the eye." The technique, which was closely adhered to, was described as follows:

A small, curved-eye needle threaded with fine silk (6-0) was introduced in the sclera 2 or 3 mm. behind the limbus above the horizontal line, passed into the anterior chamber, under the base of torn iris, and out through the cornea. The needle was then removed. A similar suture was passed below the horizontal line. An incision was made in the limbus with a narrow keratome between the points of entrance of the two needles in the sclera. Through this opening a small, blunt iris hook was introduced; the hook engaged the thread between the iris and cornea, pulling the end of the thread out of the cornea, back into the anterior chamber, and through the wound out of the eye. The threads were then tied, so that the torn base of the iris was gently brought back to the sclerocorneal junction.

This operation was performed on October 10, 1943, about six months after the injury. Atropine was instilled, and the eye bandaged. The postoperative course was uneventful. The eye was redressed on the second day, and atropine instilled daily thereafter. The sutures were removed on the eighth day, and the child was discharged two days later. On January 13, 1944, the traumatic cataract was removed by a discission, and again by a capsulotomy on June 29, 1944. The result was a clear, fairly round pupil. An approximate correction with +12.00D. sph. gave 20/70 vision.

Comment. Reports in the literature on the surgical treatment of traumatic iridodialysis are not numerous. Most of the

operators have used the method of iris incarceration, either by pulling the base of the iris into the limbal incision, or by suturing with one or more sutures a few of the iris fibers to the scleral junction immediately behind the cornea. Ben Witt Key, in 1934, reported four eyes successfully operated on by the suture method; and Goldfeder, in 1932, reported two cases treated by the method of iris incarceration. Spaeth described a similar operation, also based on the principle of iris incarceration by sutures, which he prefers to perform under a conjunctival flap to prevent infection. Wheeler looks with disfavor on the method of iris incarceration which "drags the iris into the limbus wound in such a way as to form an iris prolapse." Neither does he approve of sutures, on the general ground that, "sutures should not be passed through eye structures unnecessarily." He maintains that "an attachment can be easily and permanently secured by simply carrying a tiny shred of tissue from the torn edge of the iris very slightly into the limbus wound." The Jameson operation does not incarcerate the iris between the lips of the wound, but brings the torn surface in contact with a freshened surface, within the anterior chamber. Reattachment takes place by agglutination through a plastic exudate thrown out from the iris at the point of contact.

Since they had had no previous experience with the surgical treatment of traumatic iridodialysis, they do not presume to judge the merits of this or other methods. In this particular case, they were fortunate in obtaining the desired result with the method described. When the patient was last seen, two weeks previously, about 18 months after the operation, there were no signs nor symptoms of any late complications, and the iris was still intact. The right eye remained normal throughout.

In conclusion they stated that they were

keenly conscious of the fact that this operation, like any other intraocular operation, was not without its potential risks, and should not be undertaken lightly. The operation should not be performed when the dialysis is small, or when the defect is concealed by the lids. But when the defect is large, and the cosmetic effect is such that it can be a source of real embarrassment, the operation is justified.

Dr. Barlow said that one of the possible dangers would be injuring the lens during the operation, thus producing a traumatic cataract. In this case, of course, the lens was already opaque, and this possibility was not faced. However, when the lens is clear, great care must be exercised not to injure it.

Another possible danger is infection. This, of course, is something which is feared in every intraocular operation. However, if the operation is done under aseptic conditions, and the culture is negative, the danger of infection should be no greater than in any other operation—cataract extraction for example—especially in view of the variety of sutures so popular in modern cataract surgery.

Another possible danger which should be mentioned is late secondary glaucoma. This is a possibility both after the traumatic iridodialysis and after the operation for its correction. However, as far as he knew, Dr. Barlow said that no such case of secondary glaucoma following the surgical correction of traumatic iridodialysis has ever been reported.

Discussion. Dr. Warren S. Reese said that before Dr. Barlow explained about the keratome incision, it occurred to him that it might be possible to avoid a keratome incision by using a self-threading needle, and two sutures, one of which would be passed between the two strands of the first just beyond its exit from the iris. The needles could be removed following the perforation of the cornea. The suture could then be pulled back into the

anterior chamber, one acting as a plug and preventing the other from slipping back through the iris.

Dr. James S. Shipman stated that in reading the technique of this operation, which is so well described and illustrated in "Surgery of the eye," he could not understand why the cornea would not be badly scarred in cases of iridodialysis sufficiently large to justify this operation.

In any iridodialysis that is large enough to justify this operation, it would be necessary to bring the needles out through the cornea fairly close to the center, and since these go all the way through the cornea, he does not see how permanent scarring with an accompanying reduction in vision can be prevented. Certainly, infection is also a danger, since the needles and sutures go out through the cornea, and the free suture has to be again pulled back into the anterior chamber. Extreme care should be taken to prevent contamination of this suture by the lashes, skin of the lids, and skin of the face. His experience with suturing the cornea has been that one is more likely to get some sloughing, with infection about the sutures, than when suturing is done through the sclera.

Regarding the conjunctival flap, he said he does not feel that this is necessary because it is likely to dam up the secretions and give rise to more sloughing about the sutures. He stated that this operation is a very ingenious one, and one which on several occasions he had been tempted to try but had refrained for fear of the damage which it might do to the cornea. It has been pointed out by Dr. Wiener that small iridodialyses do not cause sufficient trouble to warrant the dangers of this operation, and the very extensive ones certainly bring up the question of corneal scarring. He asked Dr. Weiner to relate just what the final amount of scarring in the cornea was.

Dr. Herman L. Weiner, in closing, an-

swered that they were quite aware of the fact that the cornea must have scars following an operation of this type. A rather fine round needle was used with no. 6-0 silk. The resulting scars were pin-point and could be seen only under bright illumination and slitlamp examination. Vision was not impaired by the scars.

RE-EVALUATION OF THE HERBERT FLAP OPERATION FOR GLAUCOMA

DR. LOUIS LEHRFELD stated that Lt. Col. H. Herbert of the Indian Medical Service contributed many splendid articles on the surgical treatment of glaucoma from 1903 to 1934.

Of the many types of operations suggested by Herbert, the flap operation, sometimes known as the trapdoor operation, is revised by the author for cases of absolute glaucoma. Seven cases were reported, two of which were especially related in detail because of the splendid results in reducing the intraocular pressure.

Herbert's original operation is described as an anterior sclerotomy in which the horizontal incision is made in the sclera at varying distances from 1.5 to 3 mm. above the limbus. Two vertical incisions are made, one at each end of the horizontal incision toward the cornea; the effect is of an inverted U-shaped trapdoor covered by the overlying conjunctiva.

The modification suggested by the author is in the location of the trapdoor—namely, in the position of the pars plana of the ciliary body, which he describes as the silent area of the eyeball. The location has the advantage that it is sufficiently distant from the lens and from the corneoscleral junction, where surgery in itself leads to many complications and unsuccessful results.

He recommended a modified Herbert trapdoor operation for the acute and

chronic forms of glaucoma. The following reasons were offered: (1) the simplicity of the technique; (2) the lack of complications; (3) its effectiveness in reducing the intraocular pressure gradually; and (4) because it is located in the vitreous segment of the globe, remote from the canal of Schlemm, the iris, the lens, the root of the iris, and corneoscleral junction which in most instances have already been damaged by increased intraocular pressure.

A number of lantern slides were exhibited illustrating the Herbert operation, and the new point of approach suggested by Dr. Lehrfeld.

SYMMETRICAL DEFECTS IN THE LOWER LIDS ASSOCIATED WITH ABNORMALITIES OF THE ZYGOMATIC PROCESSES OF THE TEMPORAL BONE

DR. IRVING H. LEOPOLD, DR. FRANCIS MAHONEY (by invitation), and MABEL LEE PRICE, M.S. (by invitation) stated that symmetrical defects in the lower lids associated with bilateral absence of the zygomatic processes were reported in a child, in the child's mother, and in the mother's father. A pedigree was traced for this family which suggested the hereditary nature of these defects, and that the responsible gene is a dominant one. X-ray studies established the fact that the deficiency of the zygomatic process is associated with the lower-lid deformity and, in addition, demonstrate that the osseous deficiency is similarly transmitted. The presence of normal facial bones other than the zygomatic process of the temporal bones, and normal clavicles would exclude these cases from the cleidocranial-dysostosis group.

Although the lid defects in the three cases presented are very similar to those observed by others, the bony defects are chiefly of the zygomatic processes of the temporal bones, and not of the zygoma

bones, as has been described in the earlier reports of others. None of the previous reports noted an associated osseous deficiency in other members of the respective families.

Dr. Francis Mahoney mentioned that there are numerous types and groups of dysostoses of the cranial bones. The commonest are the meningocele and encephalocele, and less common are those cases with a congenital absence of the superior orbital wall. In these cases there is a characteristic pulsation of the globe synchronous with cardiac pulsations. The least common is the "Lückenschädel" or lace-work skull. This is the most severe and extensive of the dysostoses of the skull. None of these are hereditary in nature.

There have been three types reported with a hereditary link. This group of cases is a fourth type in this series.

The most spectacular of these, of course, is hereditary cleidocranial dysostosis, where there are associated cranial defects in individuals with deficient or absent clavicles. Some of these people can bend forward, and touch their two shoulders together. They have, as Dr. Leopold described, changes in the facial bones, but these changes are in the maxillae, with deficiencies in the maxillary teeth and malocclusion with the mandibular teeth.

Another type is hereditary craniofacial dysostosis. This appears to be a group in which the skull and facial-bone changes are very similar to those presented in cleidocranial dysostosis but the changes in the clavicles are absent.

The third group, which seems closest related to this group, comprises the hereditary ectodermal dysplasias. In these cases there is a deficiency in the sweat glands and scanty or missing hair. Usually the upper incisor teeth are missing. The skull has a hydrocephalic appear-

ance with a "too large head upon a too small face."

In this group of cases the cranial bones were well formed. There was no disproportion between the bones of the vault and the bones of the face. There was no deficiency or malocclusion of the teeth. The clavicles were normal. The only bony deficiency was the absence of the zygomatic processes of the temporal bones. However, the changes in the lower eyelashes, and in the glands around them would point to some link with the hereditary ectodermal dysplasias.

INTRAVITREAL PENETRATION OF PENICILLIN AND PENICILLIN THERAPY OF INFECTIONS OF THE VITREOUS

DR. IRVING H. LEOPOLD stated that experimental studies with rabbits revealed that intramuscularly and intravenously administered penicillin in a concentration of 4,000 units per kilogram failed to produce detectable concentrations of penicillin.

Prolonging the length of time that penicillin remained in the blood stream by employing a penicillin-gelatin-vasoconstrictor preparation failed to increase the intravitreal penetration of penicillin from the blood stream in the normal rabbit eye.

Subconjunctival injection of penicillin and injection of the substance into the anterior chamber produced detectable concentrations of penicillin in the vitreous in the normal rabbit eye.

All methods of administration produced higher concentrations of penicillin in the vitreous humor in the rabbit eyes with infection of the anterior chamber than in normal eyes.

Theoretically adequate concentrations of penicillin in the vitreous were obtained with administration of penicillin by subconjunctival injection and by injection into the anterior chamber in the inflamed

rabbit eye. Such levels were adequately maintained for three hours after one injection.

Higher concentrations of penicillin in the vitreous were obtained in eyes with iridectomies than in normal eyes after injections of penicillin into the anterior chamber.

Penicillin intravenously administered failed to stop the progression of experimentally induced ectogenous infections of a vitreous caused by a penicillin-sensitive strain of *Staphylococcus aureus*.

Repeated conjunctival injections of penicillin and injections into the anterior chamber halted the progress of intravitreal infection due to *Staphylococcus aureus* in 4 of 10 rabbit eyes.

Intravitreal injections halted the progress of ectogenous infections of the vitreous due to *Staphylococcus aureus* in all eyes receiving one injection consisting of more than 500 Oxford units of penicillin. Lower concentrations than this, including five units per injection, were partially successful.

Discussion. Dr. W. Zentmayer said that Rycroft quite recently reported the results obtained with penicillin by the ophthalmologists in British North Africa and Central Mediterranean Forces. The study is largely clinical, and this may explain the apparent disagreement between their results and those given here by Dr. Leopold. From their findings penicillin does not enter the ocular media when given by intramuscular injection. Such injections do not influence the course of deep infections of the eye. The eye will tolerate large concentrations of penicillin injected into the media, but such concentrations do not control deep infections.

Dr. H. Maxwell Langdon said that the organism with which these experiments were done was selected especially for its nonresistant powers to penicillin. It would be interesting to know the effect on other organisms in the vitreous. Those

resistant to penicillin, of course, have been fairly well recognized and classified, but, as he understands it, some are more readily affected than others. Without cultures, of course, these could not be identified; so it is bound to be more of a trial-and-error procedure in the ordinary clinical case. It is a valuable piece of work, and possibly may result in the saving of eyes which otherwise might be given up as hopeless.

Dr. Irving Leopold, in closing, said that he, too, had found Colonel Rycroft's article very discouraging. All of Rycroft's cases of vitreous inflammation were due to intravitreal foreign-body penetration. Only two of these cases showed improvement, and these two were ones in which the offending foreign bodies were removed. In not one did aqueous or vitreous cultures reveal that the exciting, inflammatory agent was a penicillin-sensitive organism.

In all of Rycroft's cases intravitreal penicillin injections were not made until the inflammatory process had become well established. In the experiments on rabbit eyes, therapy was instituted two hours after vitreous inoculation with *Staphylococcus aureus*. Von Sallmann's studies indicate that little can be expected from direct intravitreal injection of penicillin later than 12 hours after inoculation of the penicillin-sensitive organism, but that excellent results may be obtained by earlier institution of therapy.

Rycroft's studies on human eyes showed, as did the experimentation on rabbit eyes, that intramuscularly administered penicillin did not produce detectable levels in the vitreous of normal eyes. He could not detect penicillin in the vitreous of inflamed human eyes after intramuscular administration; whereas, the vitreous of inflamed rabbit eyes did possess detectable but inadequate concentrations of penicillin.

It is known that the permeability of

rabbit ocular capillaries is greater than that of human capillaries in inflammatory states. For example, Brown and Nantz pointed out that the rabbit's secondary aqueous contains considerable fibrin; whereas, the adult human eye shows very little if any fibrin in its secondary aqueous. This permeability difference must be kept in mind in drawing analogies between the data accumulated by experimental studies on rabbit eyes, and that of human cases.

The *Staphylococcus aureus* organism was used in these studies because it is extremely sensitive to penicillin. The main purpose of the experiment was to compare the possible chances of controlling the vitreous infections by the various methods of administration. He said he believed that the experimental data have shown that systemic therapy is not adequate. Rycroft's experience would bear this out. The experimental studies indicate that direct intravitreal injections may be effective if one treats the infection early enough. This latter observation can be said to apply only when the vitreous infection is due to a penicillin-sensitive organism.

Dr. Leopold said he agreed with Dr. Langdon that these experiments are only an introduction to the problem of treating vitreous infections, and much more work will have to be done both in the laboratory and clinically before the ideal method of treating vitreous infections with penicillin will be known.

PENICILLIN IN OPHTHALMOLOGY (PRACTICAL VIEWPOINTS)

DR. LUDWIG VON SALLMANN limited his report to practical suggestions as to the

use of penicillin in ophthalmology and distinguished between various types of administration depending upon the site of the infection. Surface infections of the lid border, conjunctiva, and cornea benefit from the use of penicillin in aqueous solutions, ointments, and gelatin discs when the strain of the microorganism is relatively susceptible. Data were presented on dosage, frequency of application, and the advantages of certain ointment bases and penicillin salts. For acute ectogenous infections of the anterior segment of the eye, iontophoresis and the placing of cotton packs in the conjunctival sac secure adequate concentrations of penicillin in the eye, whereas subconjunctival injection does not. Another method of treating infections of the anterior segment would be by replacing the aqueous with a penicillin solution containing 1,000 to 2,000 Oxford units. Gratifying results were observed when the infection had not spread to deeper parts of the lens or to the vitreous space.

Infections of the lens and vitreous can be attacked by direct injection of penicillin in a concentration that does not cause damage. Encouraging clinical results are at hand in cases in which the infection was not older than 48 hours. In more advanced infections the inflammation may subside but the function will not be restored. Systemic therapy can be used as an adjuvant in ectogenous infections but is of significant value in metastatic infections.

DISEASES OF THE MACULA

DR. RALPH I. LLOYD surveyed this subject, demonstrating with kodachrome slides the condition of the fundus in his comprehensive talk. He emphasized especially the differentiation between hereditary and acquired disease of the macula and discussed at some length the subject of eclipse blindness.

George A. Graham,
Associate secretary-treasurer.

OPHTHALMOLOGICAL SOCIETY OF MADRID

DR. MARÍN AMAT, *president*
SCIENTIFIC SESSION

CHOLINE IN SERPIGINOUS ULCERS OF THE CORNEA

DR. ENRIQUE MARÍN ENCISO used choline in his clinics at the Provincial Hospital of Ciudad-Real, based on the article of Drs. T. J. Dimitry and P. Aznar, entitled "The use of choline in cases of ulcer and leukoma of the cornea" published in the American Journal of Ophthalmology, for January, 1945, and gave an account of its favorable results in his doctor's thesis, which was read last October.

Dr. Marín Enciso confirms all findings in his doctor's thesis, and adds eight clinical histories of patients with serpiginous ulcer of the cornea, in which a 1-percent solution of choline, injected several times a day, produced a rapid cure with a minimum of scar tissue.

He called attention to the use of choline with mercurochrome which acts well in combination. He has used a 1-percent solution of choline with good results in subconjunctival injections as well as in the conjunctival sac. Dr. Marín Enciso stated that it was unnecessary to remove the tear sac in any of his patients or perform other types of dacryocysto-rhinostomy. Had these operations been performed, success would have been still greater in that the condition would have improved more quickly.

CHOLINE IN OPHTHALMOLOGY

Dr. Marín Amat, impressed by the work of Drs. Dimitry and Aznar, had also used choline in a 1-percent solution in many cases of serpiginous ulcer of the cornea, and obtained wonderful results.

Dr. Marín Amat used choline and mercurochrome in combination, having noted that choline, which has a tremendous penetrating power on the tissues, so enhances the action of mercurochrome that the bactericidal effect is increased. He also used choline in cases of incipient panophthalmitis, in purulent iritis, in infection of the filtering tissues following Elliot corneoscleral trephining, and in the post-traumatic suppurations of the eyeball.

Dr. Marín Amat has also used a solution of choline in cases of leukoma of the cornea caused by lymphatic ulcers, for corneal bullae, and for serpiginous ulcers of the cornea, and he reported four clinical histories showing good results.

Dr. Marín Amat has had no experience with choline in old cases of leukoma because of the brief period of use. However, judging from the statements of the American doctors, and by what he has verified in recent cases, he believes it to be of great help. He has likewise used choline in the infiltration of cholesterol in the cornea, having had better results than he had obtained with all other general as well as local treatments.

He was equally impressed by an article by Drs. Dimitry and Lombardo, "The lipotropic effect of choline in retinal tuberculosis," which was published in the American Journal of Ophthalmology for August, 1945. This article referred to a case of hemorrhages and tubercles in the retina, which in the space of two weeks, under the administration of 25 centigrams of choline, three times daily, disappeared completely. Dr. Marín Amat used choline in two cases of relapsing hemorrhages of the vitreous. Improvement resulted in one case, but the result in the other case was not known, as the patient did not return.

Since chlorhydrated choline is extremely deliquescent, it must be used in a water-diluted solution of proper dosages. The

best treatment is 20 drops (taken 15 minutes before each meal) of chlorhydrated choline—5 grams in 20 grams of distilled or redistilled water. Dr. Marín Amat has used 1 c.c. of choline repeatedly, subconjunctivally, in a solution of 1:300, with satisfactory results. The injection is entirely painless.

CAN GLAUCOMA BE AN OCCASIONAL CAUSE OF DEATH?

PROF. B. CARRERAS DURAN reported two cases in which glaucoma caused death. The first, an acute case of glaucoma, accompanied by vomiting, occurred in the consultation room of the physician. The patient, through the strain of vomiting, had died of an apoplectic attack. In

the second case, of a patient with staphyloma, a hemorrhage occurred which persisted in spite of all medical and surgical means employed to stop it, causing the patient's death.

BILATERAL LUXATED LENSES

DR. BARTOLOZZI presented a woman who belonged to the service of Professor Carreras of the Madrid Faculty of Medicine. Both crystalline lenses were luxated into the posterior chamber coincident with lesions of the base of the eye of the hereditætic type. The etiology had not been established. It was still being studied.

Apropos of this case, Drs. Marín Amat and García Miranda told of analogous observations made by them.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois*; Society Proceedings to Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. Herbert Haessler, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

DR. W. H. CRISP AN APPRECIATION

Dr. William H. Crisp's editorial in the January issue, announcing his retirement as editor of the abstract department, should not go unnoticed. Only those of us who have been in close association with Dr. Crisp in Denver and those actively engaged in the publishing of the Journal have any conception of the effort that he has expended. But anyone may look through the ophthalmic literature and note the hundreds of original papers, brilliant editorials, and abstracts that he has written and the thousands of abstracts and original papers that he has edited.

The abstract department under Dr. Crisp's guidance has not only given the reader a rapid survey of the important ophthalmic literature, but has lightened the task of searching through the literature for knowledge on a particular subject. Only the combination of a brilliant mind, a desire for perfection, and a disregard for financial considerations could permit such a public-spirited accomplishment. Dr. Crisp's ability to read many languages has been a vital aid in the accuracy and completeness of the abstract department.

Dr. Crisp speaks of the "evening of life," but those of us closely associated

with him notice no evening of mental vigor and enthusiasm. We wish him many years of successful practice and are happy that he now has more time to direct his activities to the artistic endeavors in which he has perfected himself. We, of the Colorado Ophthalmological Society, wish publicly to express gratitude to a colleague "who worked that we might know and that patients might profit."

Members of the Colorado
Ophthalmological Society

A NATIONAL PROGRAM FOR TRAINING IN OPHTHALMOLOGY

Quite admirably, the emphasis of this Journal's editorial comments in recent months has been upon postwar training in ophthalmology. There is common agreement as to the urgency of the problem, but the conclusions as to how much may be accomplished are scarcely optimistic.

World War II has intensified a problem which existed before the war. In this, as in other fields, it has accumulated demand and diminished supply. The country as a whole has never had an adequate and unified program of training in ophthalmology. Perhaps the war will make it possible for us to accomplish something which we have not achieved before.

A worthy effort is that of Harvard University to provide, for a maximum of thirty postgraduate students, a two-months course in fundamentals (much of which Lancaster reminds us can be taught by lectures, reading, and quizzes) followed by a clinical course of one month. These short programs should be stimulating to young ophthalmologists whose time was badly wasted during the war and who are eagerly looking for refresher courses. By themselves, the two Harvard courses cannot, it is obvious, create first-class ophthalmologists.

Vail reminds us that of fifty-nine class-A medical schools not more than six are giving or are planning to give basic courses in ophthalmology. Some schools are offering courses of six or nine months. Lancaster frankly quotes the American Board of Ophthalmology as consistently urging that "short courses are an abomination—unsound pedagogically and productive of a poor grade of practitioner."

Yet short courses, rightly planned, can teach a great deal. The student who gets least out of a short course is he who has done little or no systematic reading before beginning the course. The student who has read systematically, deliberately, and intelligently may absorb much in a short time, and it is doubtful whether any student should be allowed to follow a clinic without being able to show that he has previously pursued such a thorough course of reading. This is especially true with regard to refraction, which is the economic basis of a beginning practice in ophthalmology, but which is perhaps less systematically approached by the average student than any other part of the subject.

More than ever before, governments are now disposed to cooperate in the provision of education for various professions. It is obvious that the most successful utilization of this governmental tendency is likely to occur under adequate guidance and pressure from within the group of educators in ophthalmology. In spite of the general dislike for governmental interference in the field of medicine, it is probable that any relatively adequate scheme will have to depend in large measure upon government financing. It is worth the nation's while to contribute to institutional and individual financial need in pushing the educational program in ophthalmology.

So far as clinical facilities are concerned, we may have to meet the emergency by accepting less of thoroughness

than we might have demanded before the war, or than we shall demand when the emergency is past. Many intending ophthalmologists will continue to pick up their knowledge rather casually, through assistantships or through courses by commercial clinics.

Perhaps we are attempting for a few an excess of thoroughness as compared with the magnitude of the problem as a whole. Mann makes the interesting remark that "on one side of the Atlantic the aim is the very thorough and complete training of a relatively few high-grade specialists, while on the other side we aim at basic instruction of a larger number for a shorter time, leaving it to the initiative of the few to obtain for themselves the final gloss and polish of academic distinction requisite for the highest grade."

In the presence of a really national problem, it seems essential to formulate a national program, partly through conference between educators and partly through coördination between educators on the one hand and departments of the national government on the other. Such a program might well represent compromise between conflicting views as to the scope of education in ophthalmology, so that an approximately uniform curriculum might be applied to different sections of the country. Or certain parts of the program might be presented in some educational centers, to be supplemented by other parts of the program in other centers. A program that is national and coördinated, rather than local and spotty, appears called for by the necessities of the situation.

A need not altogether easy to supply is that of an adequate staff of teachers. For one thing, most medical educators who are also private practitioners can do a much more thorough job away from home than in their own communities, because it is hard to escape the importunities of patients in the home area. Yet it should be

possible to create, all over the country, a staff of teachers who could afford to leave home practice for national service in ophthalmic education, perhaps several times each year. The greatest sphere of usefulness of the veteran teacher and clinician lies in handing on to another generation the results of his own study and experience.

It is to be hoped that effect may be given to Vail's frank and practical suggestion that combined residencies in ophthalmology and otolaryngology be divided into two parts, one devoted to each specialty, for experience has shown that, at least as regards ophthalmology, the educational result suffers from the combination.

W. H. Crisp.

TRIDIONE AND THE EYE

There has recently appeared in the field of therapeutics a new synthetic compound, Tridione (3, 5, 5-Trimethyloxazolidine-2, 4-dione, Abbott). This drug is being used as an anticonvulsant in the treatment of epilepsy, particularly for its inhibiting effect on *petit mal*, and on myoclonic and akinetic seizures in epilepsy, and is being prescribed for other forms of psychomotor attacks, such as the spasmodic tremors and tics of parkinsonism. The results are promising.

One of the unpleasant and disturbing side effects of Tridione therapy is the so-called "glare phenomenon" complained of by patients taking the drug in from moderate to large doses. This phenomenon is described by patients in various ways, from inability to see black on white, or colors against a light background, to complete day blindness. The symptoms disappear when the drug is stopped, but there is a time lag, probably depending on the duration of the use of the drug, which would indicate that there was some

accumulative effect. For example, one patient recently studied did not recover from the "glare phenomenon" for two weeks after the drug was discontinued.

The ophthalmic examination of these patients is an interesting experience. The phenomenon is a puzzling one that requires further investigation. Vision is normal when tested with an unlighted chart but decreases to an average of 20/100 when the chart is illuminated. On putting on dark glasses, the patient can read the letters on the chart easily, as a rule. The fields of vision, both peripheral and central, have been found to be unaffected, and the ophthalmoscopic examination reveals no detectable disorder in the ocular fundus. The color vision when tested with the Ishihara test is likewise undisturbed.

Curiously enough, the reading vision is not particularly affected, at least in the few patients recently studied, although each patient preferred to read through tinted lenses.

The group studied were willing to put up with the "glare phenomenon" because they felt better under this treatment than otherwise, and were not too uncomfortable when they wore their dark glasses and avoided bright sunlight.

It is interesting to speculate just what goes on in the eyes to produce this symptom. There is apparently no damage to the visual system—at least none that can be demonstrated. Caution is needed, however; whether or not serious harm can arise from the administration of the drug has not yet been determined. The use of large doses of vitamin A has had no influence on the symptom, nor has any other treatment, so far as is known, had any effect. Histologic studies on the optic nerves and retinas of experimental animals receiving large doses of Tridione over long periods of time have failed to reveal any evidence of damage. But it

would be wise to limit the use of the drug to those patients who show no optic-nerve disease, or who are not taking concurrently a drug that may injure the optic nerve.

This editorial is written for the purpose of drawing the attention of the ophthalmologist to this new therapeutic agent that may not be entirely innocuous to sight, and as a plea for further studies, both chemical and experimental, to determine, first, how the "glare phenomenon" is induced; secondly, what, if anything, can be done to counteract it; and, finally, if thereby any residual permanent damage is produced in the visual system. This last is most important. It would be wise, therefore, for each ophthalmologist to acquaint himself with Tridione and to be alert to discover the answers to these important questions.

Derrick Vail.

CORRESPONDENCE

DISPENSING WITH BIFOCALS

Editor,

American Journal of Ophthalmology:

The communication of Dr. L. J. Alger in the February issue of the American Journal of Ophthalmology is a timely reminder of what may sometimes be done to avoid bifocals, especially for those who find the adjustment to bifocals inordinately difficult. The method is also applicable for presbyoptic patients other than those having alternating strabismus. Although not frequently described, this method has been used occasionally by many doctors. It is really a procedure akin to that sometimes used by anisometropic patients who all their lives have relied on one eye for sharp vision at distance and the other eye for sharp vision at near.

The first such case was brought forc-

ibly to my attention some 30 odd years ago when a doctor described a patient who came to his office. An elderly gentleman brought a little granddaughter for an eye examination as directed by the school nurse. The doctor took the patient's vision and found it markedly subnormal. A flash with the retinoscope showed the child to be myopic, and the doctor told the grandfather who had accompanied the child to the examination room, that she would have to wear glasses. The old gentleman was rather put out by this information and remarked that something must be wrong with the new generation because he could read the smallest letters on the chart without any glasses, as, in fact, he could. The doctor then confidently remarked that to offset this, the little girl could read at near without glasses which the old gentleman could not do. Whereupon the old gentleman said the doctor was all wrong, for he could read the finest print at near without glasses.

A check up by the doctor on the old gentleman's eyes disclosed what the reader may have already surmised; namely, that the man had one eye practically emmetropic and the other eye about 2.50D. myopic. Without knowing it, and without loss of binocular fixation, the old gentleman was using the emmetropic eye for keen distance vision and the myopic eye for keen near vision. There was no strabismus, both eyes were fixating, but one eye took the lead for distance vision, and the other took the lead for near vision.

Such a condition, in which both eyes fixate, and only one eye focuses, does not seem to disturb vision as much as one would expect. I can speak from personal experience because my own eyes are anisometropic in a similar way. When fixating with both eyes, the nonfocusing eye does impair the vision of the focusing eye to some extent, but many a patient would rather bear this than wear bifocals. For in anisometropia especially, bifocals bring in disturbances to which the patient finds it harder to adjust himself.

Of the several difficulties encountered by bifocal wearers, I think the limitation of the field for both far and near looms large—sometimes subconsciously. Even single-vision lenses, set in a frame or mounting, restrict one's visual field. Anyone who has worn glasses, unless he is extremely myopic or astigmatic, frequently gets a feeling of relief when he removes his glasses. This is largely due to the removal of an obstruction to his visual field.

This field limitation is of course much more marked when bifocals are worn. The use of single-vision lenses set to have one eye focused for distance and the other eye for near gives the patient full binocular-field vision for far and near, with sharp monocular detail vision at both distances. It is a procedure that deserves the ophthalmologist's serious consideration.

(Signed) Joseph I. Pascal,
37 West 97th Street,
New York

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the *Ophthalmic Year Book*. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the *Journal*.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Hardy, L. H. Standard illuminants in relation to color-testing procedures. *Arch. of Ophth.*, 1945, v. 34, Oct., pp. 278-282.

Tests for defective color vision always involve three factors: the light with which to see, the subject tested, and the materials and procedures of the test. Failure to standardize two of the three factors causes invalid results in evaluating the third factor. Most tests for color vision are carried out under such nonstandard conditions that they test the illumination as much as they test the ability of the subject to distinguish colors.

The author points out the extreme variability in the color value of various illuminants, especially of daylight. Standards set up by the International Commission of Illumination are discussed. I. C. I. illuminant C is the choice for all work in testing color vision which involves the use of reflected light and, unless special conditions are

indicated, should always be utilized. A close approximation to this illuminant is commercially available at relatively low cost.

John C. Long.

Hardy, L. H., Rand, G., and Rittler, M. C. Tests for detection and analysis of color blindness. 1. An evaluation of the Ishihara test. *Arch. of Ophth.*, 1945, v. 34, Oct., pp. 295-302.

The color perception of subjects was tested with a battery of different tests designed to detect and classify color blindness. All of the examinations using pigment test material were carried out under a close approximation to I. C. I. illuminant C. The following conclusions concerning the fifth edition of the Ishihara test seem justified: The test affords a good rough device for screening persons with defective red-green vision from persons with normal color vision if a performance score of 60 is taken. No analysis as to type or extent of defect can be based on performance scores. The test yields a lower score for the deuteranopic than for the protanopic type of defective

color vision. It fails to classify the type of defective color vision and cannot be used to give a satisfactory evaluation of either the extent or the degree of the defect. Plate 4 is a practically perfect screening test when properly used.

Kayser, B. A chronic gastrointestinal ailment caused by a derangement of ocular functions. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., p. 626.

In a woman 36 years of age, a chronic gastrointestinal ailment had resisted all other forms of therapy, among which were extirpation of the appendix and gallbladder, over a period of 14 years. She was immediately relieved of all symptoms when she was given spectacles which corrected a refractive error and an imbalance of binocular coördination.

F. Nelson.

Martin, H. G. Continuation of the screen test. *Amer. Jour. Ophth.*, 1946, v. 29, Feb., pp. 196-200.

Ogle, K., and Ellerbrock, V. J. Stereoscopic sensitivity in the space eikonometer. *Arch. of Ophth.*, 1945, v. 34, Oct., pp. 303-310.

The space eikonometer has recently been shown to be a suitable instrument for the measurement of aniseikonic errors. This instrument differs from the standard eikonometer in that the measurement depends on binocular perception rather than on a direct comparison of image size. The space eikonometer is so constructed that the apparent orientation of test objects can be perceived only by binocular space perception. If an aniseikonic error exists between the two eyes, these test objects will appear incorrectly oriented to the subject. By means of suitable size lenses the relative size of the

images in the two eyes can be changed until the test objects appear correctly oriented. The magnifications introduced to achieve this objective measure the aniseikonic error.

The construction of the instrument is briefly described. Data obtained on subjects are presented and analyzed. The authors conclude that the results of this study of sensitivities emphasize the accuracy of the space eikonometer for the detection and measurement of aniseikonic errors. John C. Long.

Simonson, E., Blankstein, S. S., and Carey, E. J. Light and dark adaptation. *Amer. Jour. Ophth.*, 1946, v. 29, March, pp. 328-340. (8 tables, references.)

Slataper, F. J. Accommodation of presbyopia and its correction. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 389-397.

The correct addition for near vision in presbyopia depends primarily on the amount of available accommodation and secondarily on the selection of the best fixed distance for near work.

In reporting a tremendous amount of research work on the subject the author's conclusions are that:

1. The correct estimation of the patient's total accommodation is the most important factor in the correction of presbyopia with a glass for near work.
2. It is necessary to use three types of tests to measure accurately the total accommodation in many patients: (a) The near blur test—after Duane; (b) The "reads best" test—the most common method; (c) The + and -1.00D. spheres average-readability test; (d) The + and -0.50D. spheres coöperation test will show the cause in case of failure.
3. The normal reserve accommodation for all near work is exactly 1.00D.

4. The available accommodation for near work is the total accommodation less 1.00D.

5. The best fixed distance for close work depends on the following factors: (a) visual acuity, (b) nature of occupation, (c) muscle balance, (d) length of arms, (e) monocular or binocular vision, and (f) long-established reading habits.

R. W. Danielson.

Sloan, L. L. Atypical achromatopsia. *Amer. Jour. Ophth.*, 1946, v. 29, March, pp. 290-294. (3 tables, 3 figures, references.)

Sloane, A. E. and Gallagher, J. R. Evaluation of stereopsis. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 357-359.

Increasing use of visual tests in the field of personnel selection, special military needs, and the rapid expansion of aviation have stimulated interest in techniques which measure stereopsis.

The entire student population of a boys' preparatory school was given a thorough ophthalmic examination, and from this group of 720 boys 186 who fulfilled the following requirements were selected for the tests of stereoscopic ability: normal color vision, a normal external ocular condition, normal fundi, normal pupils, a visual acuity of 20/20 in each eye, less than 1.5D. of hyperopia, less than 1.25 prism diopters of hyperphoria, less than 4 prism diopters of exophoria and less than 6 prism diopters of esophoria at 20 feet (6 meters); less than 6 prism diopters of esophoria and less than 8 prism diopters of exophoria at 16 inches (40 cm.), and less than 1.00D of astigmatism. Hyperphoria was measured with the Maddox rod; exophoria and esophoria at 20 feet with the Maddox rod and the cover test, and at 16 inches

by von Graefe's prism test and the cover test.

The distributions of the averages of three responses to each of these tests are given, and the higher coefficients of self-reliability between trials on the Verhoeff test are offered as evidence of the superior efficiency of this test. The Verhoeff test is the more sensitive in detecting persons with poor stereopsis. The essayists believe that the Verhoeff test yields a superior estimate of acuity of binocular stereopsis. However, the value of the Howard-Dolman technique in the appraisal of aptitude for activities which require a number of attributes, should be kept in mind.

OCULAR MOVEMENTS

Lijó Pavia, J. Heterophoria and the orthofusor. *Rev. Oto-Neuro-Oft.*, 1945, v. 20, Sept.-Oct., pp. 106-111.

Horizontal heterophoria not exceeding 14 degrees should be treated with the orthofusor. This instrument employs stereoscopic photographs, polarizing light, and polaroid lenses. As in a major amblyoscope, each eye can be made to see a separate picture, and by use of prisms the apparent deviation of the eyes can be measured and the phoria treated. Pictures varying in complexity are employed to train and develop binocular single vision. (1 drawing.)

Edward Saskin.

Walker, J. P. S. Operation for correction of paralytic external (lateral) rectus palsy. *Brit. Jour. Ophth.*, 1945, v. 29, Sept., pp. 477-479.

Two cases are reported in which a modified Lancaster operation for the correction of palsy of the external rectus was done. The internal rectus

was recessed and stitched to the sclera, slightly anterior to the equator. The performance of this recession differs from that of the Lancaster operation. The external rectus was then resected and advanced after the outer third of the superior and the inferior rectus had been stitched to the stump of the insertion of the external rectus.

The outcome of both operations was entirely satisfactory. Synoptophore readings, taken before and after operation, may serve as a guide in other cases. They show that a large angle (45° and 35°) may be overcome and that almost daily improvement is obtained by orthoptic training after the operation.

It is the author's conviction that an advancement should never be performed without a recession of the opposing muscle, even though the recession may have to be only part of the way between the insertion and the equator. (References.)

conjunctivitis. *Endonasal tuberculin.* *Rev. Oto-Neuro-Oft.*, 1945, v. 20, Jan.-Feb., pp. 1-8.

In a previous report the authors described the use of endonasal tuberculin in phlyctenular conjunctivitis. It was particularly applicable in children and in those adults in whom a minimal systemic reaction was desirable. Four new cases are reported in this communication. The patients were treated as before, beginning with a dilution of 1:100,000 and increasing to 1:10,000. All patients were female, from 8 to 19 years of age, and had pulmonary tuberculosis and phlyctenular conjunctivitis. After therapy there was systemic and ocular improvement. (1 series of drawings.)

Edward Saskin.

Meenan, P. N. **The etiology of trachoma in Ireland.** *Irish Jour. Med. Sci.*, 1945, Nov., p. 670; and Dec., p. 703.

The author presents a preliminary report of an extensive laboratory and clinical study of trachoma in Ireland. He bases his conclusions on the reports of investigators in Ireland and the United States. Most Irish investigators believe that the etiologic agent is a virus rather than a rickettsia. The virus seems to be related to the viruses of psittacosis, lymphogranuloma venereum, and atypical pneumonia. In 49 patients studied, inclusion bodies were found in 19 percent of the eyes in stage I, in 12 percent of those in stage II, and in 5 percent of those in stage III. The author suggests that there may be an unrecognized stage in the life cycle of the virus during which most of the tissue damage is done and in which it might be most susceptible to the sulfonamides.

Morris Kaplan.

Minton, J. **Eye diseases in the East.** *The Practitioner*, 1945, v. 155, Sept., p. 176.

The author served as military ophthalmologist in Iraq, India, and Ceylon and presents his observations and some practical suggestions for treatment of the eye conditions encountered. Great epidemics of virulent conjunctivitis occur twice each year and cause much blindness from severe corneal disease. Many of the patients are children infected by direct contact with other children who have gonorrheal or diphtheritic conjunctivitis. Instillations of sulfapyridine powder in cod-liver oil were given. Trachoma was found in 60 percent of people of all ages. In India, he found a great number of children suffering from vitamin-A deficiency, with serious corneal involvement. In India, an epidemic of punctate keratoconjunctivitis ascribed to virus infections occurs each year. Its morbidity is very high, and treatment is quite unsatisfactory. It is interesting to note the extremely low incidence of these diseases among the Europeans living in the areas. Morris Kaplan.

Paez Allende, F. **Neurofibromatosis of the bulbar conjunctiva.** *Anal. Argent. Oft.*, 1945, v. 6, Jan.-Feb.-March, pp. 6-17.

Neurofibroma may involve the central nervous system, the outer coverings of the body, and the osseous system. In the eye, the skin of the lids may be invaded with a resultant lid ptosis, or the tarsal and bulbar conjunctiva may be the seat of the affection. In a girl, 18 years of age, only the bulbar conjunctiva was involved. Co-existent with the disease, there were epilepsy, corporal asymmetry, intracranial derangement, skeletal lesions, skin tumors, partial alopecia, and a

mild mental retardation. The disease affected the right eye only and involved the bulbar conjunctiva above the limbus up to the caruncle. The lacrimal gland was hyperplastic. A ptosis of the upper lid was present, and there was a punctiform macula in the upper part of the cornea. Vision was reduced to 1/6, and could not be improved. The visual field was within normal limits. Biopsy of the tissue corroborated the diagnosis of neurofibromatosis. The author has considered extirpation of the bulbar growth followed by a buccal mucosa graft. (7 illustrations, bibliography.) Edward Saskin.

Rosen, E. **Heterogeneous conjunctival transplantation.** *Amer. Jour. Ophth.*, 1946, v. 29, Feb., pp. 193-195. (3 figures, references.)

Ventura, Altino. **The surgery of pterygium.** *Rev. Brasileira de Oft.*, 1945, v. 4, Dec., pp. 138-142.

The author deals especially with the conjunctival autoplasty of Paulo, Jr., according to which method over 100 patients have been operated upon in the Recife and other Brazilian clinics. Of these, 52 cases were reexamined at least six months after the operation and are here surveyed. The McReynolds operation, previously employed, had given a slightly higher percentage of recurrences than the Paulo procedure. The paper was discussed by Pedro Falcão, who dismissed the idea that pterygium is produced by chronic inflammation of the nasal or paranasal region or by external irritation from dust and wind; by Moacyr Alvaro, who pointed out that Dimitry of New Orleans has found a greater incidence of pterygium in Louisiana, without wind and dust, than has been reported from drier states of the North Ameri-

can Union; and by several other speakers.

CORNEA AND SCLERA

Blondis, R. R. Superficial pigmentation of the cornea. *Amer. Jour. Ophth.*, 1946, v. 29, March, pp. 316-323 (4 figures, references.)

Bonnet, P. Two new observations on diffuse papillomatous hyperplasia of the cornea developing in old trachomatous pannus. *Jour. d'Ophth.*, 1944, v. 3, No. 3, p. 239.

Two new observations of diffuse papillomatous hyperplasia of the cornea are reported, one in a woman of 47 years with trachoma since the age of 14 years, and the other in a woman of 66 years with trachoma since she was 25 years old. In each case the tumor involved only the cornea. The limbus and bulbar conjunctiva were free. The author believes that chronic irritation is necessary for the formation of these tumors and that in his patients trichiasis was the main source of irritation. He recommends temporary closure of the lids by blepharorrhaphy after extirpation of the tumor to eliminate irritation of the cornea.

Phillips Thygeson.

Bonnet, P. Interstitial keratitis and the Argyll Robertson pupil. *Jour. d'Ophth.*, 1944, v. 3, No. 3, p. 175.

The author states that the Argyll Robertson pupil is the most rare of all the stigmata of congenital syphilis and that the most common pupillary disturbance is internal ophthalmoplegia. He reports the case of a woman, aged 23 years, with congenital syphilis. She had had an interstitial keratitis at the age of 10 and had received regular

antisyphilitic treatment. She showed persistent synechiae. Under the slit-lamp the absence of the light reflex and the presence of a reaction to accommodation convergence were easily demonstrated.

Phillips Thygeson.

Buxton, R. J. Observations on keratoconjunctivitis in military hospitals. *Brit. Med. Jour.*, 1945, Dec. 15, p. 847.

Forty-two cases of keratoconjunctivitis were examined in various military hospitals. The clinical manifestations and treatment are described in detail. The author found a toxic focus in the nose and throat in 40 percent of the patients, and a dental focus in 26 percent. In several cases, the lesion in the eye improved immediately after tonsillectomy or dental extraction. Occasionally an exacerbation of the ocular inflammation followed the removal of the focus of infection, possibly as an allergic manifestation of a bacteriemia.

R. Grunfeld.

Friede, R. Treatment of serious vitreous losses after keratoplastic operations. *Klin. M. F. Augenh.*, 1942, v. 108, Nov.-Dec., p. 717.

When the excision of a keratoplastic flap or of plastic iris membrane is accompanied or followed by the loss of a large quantity of liquefied vitreous an attempt must be made to fill the collapsed bulbus. Injection of physiologic salt solution or of vitreous from calves' eyes has been recommended. Friede found it more practical to increase the fluid content of the whole body by administering large quantities of water by mouth. He observed a very rapid replacement of the lost vitreous. Even after complete collapse of the globe, normal configuration was re-

gained within two to three days. One case is reported. F. Nelson.

Gomensoro, J. B., and Isola, W. The syndrome of blue scleras. *Rev. Oto-Neuro-Oft.*, 1945, v. 20, Sept.-Oct., pp. 111-119.

A case of blue sclerotics in an individual manifesting general debility and bone disease is described. An academic discussion of the blue-sclera syndrome is presented wherein many investigators are quoted. The characteristic changes in the eye are associated with disturbances in other parts of the body such as fractures, deformities, and radiologically demonstrable alteration of bones; weakness of the ligaments; neuro-muscular debility; deafness; endocrine disturbances; arterial hypotension; and syndactyly. The heredity of the syndrome is discussed. Its development is thought to be a result of a disturbed development of the embryonic tissues, particularly those of the mesenchyme, and also of an imbalance of the endocrine system. Treatment is essentially symptomatic, although thyroid and anterior pituitary extract have been administered with equivocal results. (References.) Edward Saskin.

Harley, R. D. Ocular leprosy in Panama. *Amer. Jour. Ophth.*, 1946, v. 29, March, pp. 295-316. (19 figures. references.)

Illig. The use of digestive ferments in serpiginous corneal ulcer. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., pp. 618-620.

In this brief preliminary report the author discusses the possible usefulness of ferments in the treatment of corneal ulcer. He did some experimental work with rabbits and treated a few patients. He used pancreatic

ferment because it is active in an alkaline medium. A standard ointment used in dermatology is tolerated by the normal eye without signs of irritation. In an aged woman whose eye was considered all but lost because of a serpiginous corneal ulcer, the ulcer became clear after three applications of pancreatic-ferment ointment, and the eye healed in a few days more. In two other women, the eyes reacted equally favorably.

Pancreatic ferment does not affect the intact cornea, but promptly dissolves necrotic corneal tissue. Pneumococci were either killed by the ferment or rendered avirulent. F. Nelson.

Morate, F. H. Acute keratitis fugax. *Rev. Oto-Neuro-Oft.*, 1945, v. 20, June-July, pp. 62-65.

In a sanatorium for bacillary diseases, 27 patients suddenly developed an acute, transitory keratitis. No etiologic agent was isolated, and it did not seem likely that the lesion was a manifestation of a reaction to an allergen or a therapeutic agent. The lesion was usually visible for about nine hours; the subjective symptoms lasted but a few minutes. The pericorneal injection was most marked at the 3- and 9-o'clock locations; the corneal infiltration was usually punctate though it was occasionally linear, and corneal defects could be stained with fluorescein in one half of the eyes; diminished corneal sensibility lasted for a few

minutes to a few days. Systemic treatment with gold given before the onset of the keratitis did not cause a recurrence of symptoms. No treatment was ordered because of the fleeting nature of the disease. Edward Saskin.

Paufique, L., and Bonamour, G. A new case of keratitis due to varicella. *Jour. d'Ophth.*, 1944, v. 3, No. 3, p. 255.

A young girl, recovering from varicella, developed deep parenchymatous keratitis at a time when the last skin lesions were disappearing. The keratitis was limited to the inferior temporal quadrant of the cornea and was associated with large folds in Descemet's membrane and a few corneal precipitates. There was no iris lesion. Symptoms were minimal, but vision was reduced to 1/3 and was not correctable in the affected eye. The vision of the other eye was 10/10. The keratitis was characterized by its sluggish course. The resemblance to the keratitis of herpes zoster was noted.

Phillips Thygeson:

Roper, K. L. Senile hyaline scleral plaques. *Arch. of Ophth.*, 1945, v. 34, Oct., pp. 283-291.

Senile hyaline scleral plaques must be regarded as a clinical entity characterized by the absence of clinical symptoms. The plaques are situated about 3 mm. from the limbus and 1.5 mm. to 2 mm. anterior to the insertions of the rectus muscles. They are generally rectangular but occasionally may be rounded or oval. They are most commonly seen opposite the insertion of the internal rectus muscle but occur next in frequency opposite that of the external rectus muscle. Rarely have they been observed opposite the insertion of the inferior rectus muscle. The patches appear to be somewhat

depressed. The sclera in these plaques seems to be even more rigid and resistant than average. On transillumination of the globe, the areas show as relatively clear and translucent windows. The condition apparently is not a hazard to the eye.

Advanced age is largely responsible for predisposition to the disease, since in the aged dehydration and progressive sclerosis of the connective tissue of the entire body occur. It is probably the result of a local nutritional disturbance, which, in turn, is due to arteriosclerotic changes.

The author reports five cases personally observed. There is a detailed review of the literature and a discussion of the anatomic and physiologic characteristics of the sclera. (14 photographs.) John C. Long.

Smelser, G. K., and Ozanics, V. Effect of local anesthetics on cell division and migration following thermal burns of cornea. *Arch. of Ophth.*, 1945, Oct., v. 34, pp. 271-277.

The influence of local anesthetics on the healing processes of the cornea was studied in the rat. The effect of the drugs on mitosis and cell migration of the corneal epithelium was investigated. Topical application of most anesthetics inhibits mitosis in the intact corneal epithelium when used in concentrations which produce anesthesia. The inhibition of cell division varies with different drugs, and with the method and frequency of administration. The processes of cell migration and cell division are affected differentially: cell migration may be notably retarded with little or no inhibition of cell division; other drugs inhibit mitosis but do not markedly retard cell migration. These variations make it difficult briefly to summarize the action

of the various agents. The drugs tested included solutions of cocaine hydrochloride, tetracaine (pontocaine) hydrochloride, nupercaine hydrochloride, phenacaine (holocaine) hydrochloride, butacaine sulfate, Chlorobutinal and metycaine hydrochloride. Ointments containing butyl aminobenzoate (butesin), orthoform, butacaine (butyn) sulfate, metycaine and tetracaine were used. It was found that unbuffered aqueous solutions inhibit the healing processes far more than do ointments of the same or greater strength which produce anesthesia of longer duration. Nupercaine and phenacaine ointments produce prolonged surface anesthesia and do not impair mitosis in the normal epithelium, or retard cell division or migration in regenerating corneal epithelium. John C. Long.

UVEAL TRACT, SYMPATHETIC
DISEASE, AND AQUEOUS
HUMOR

Barlow, A., and Weiner, H. L. Traumatic iridodialysis: its surgical correction. *Arch. of Ophth.*, 1945, v. 34, Oct., pp. 292-294.

The authors report the successful correction of a large traumatic iridodialysis by a method devised by Jameson. (1) A curved threaded needle is inserted into the anterior chamber through the sclera posterior to the limbus. As the needle enters the chamber it transfixes the torn iris root and is then brought out through the cornea. (2) A limbal keratome incision is made through which the thread anterior to the iris is grasped and pulled through the corneal wound. (3) The thread is tied, which brings the torn base of the iris back to the sclerocorneal junction. In the case described two threads were

used so as to form two sites of attachment to the sclerocorneal junction. The technique is illustrated.

John C. Long.

Fronimopolulos, Johann. The pathogenesis of serous detachment of the choroid. *Klin. M. f. Augenh.*, 1942, v. 108, Nov.-Dec., p. 665.

The occurrence of serous detachment of the choroid after operations for cataract and glaucoma has long been known. Its pathogenesis has been the object of research by many investigators and numerous theories have been published. The author used a 1.5 mm. trephine to produce artificial scleral and corneal fistulas in the eyes of young rabbits and dogs. Vitreous fistulas always produce an acute hypotony and deepening of the anterior chamber. The minimum decrease of tension was obtained earlier in dogs' than in rabbits' eyes. If the eyes were trephined a second time after complete recovery the hypotonic maximum was reached much earlier than after the first operation. On one group the operation was performed without anesthesia. A choroidal detachment could not be observed in any eye with vitreous fistula. The eyes usually returned to normal in eight days. The fistula was found completely closed after two weeks. Corneal fistulas were obtained by opening the anterior chamber with a keratome and punching a hole in the periphery of the cornea with Vacher's iris punch. This averts hemorrhage into the chamber, which may obscure the ophthalmoscopic picture. Iris prolapses were replaced with a spatula. The iris-lens diaphragm was always pushed forward because of the ensuing negative pressure in the anterior chamber. A sequel of the resulting hypotony was noticeable hyperemia and occa-

sionally hemorrhage in the choroid. In two thirds of all eyes with corneal fistula a choroidal detachment was observed ophthalmoscopically after about half an hour. In the remaining eyes the fundus was not seen because of hemorrhage from the iris. The onset of hypotony in these artificial vitreous fistulas was retarded by the use of cocaine and novacaine combined with adrenalin. The author believes that the continuous pull on the peripheral parts of the ciliary body causes tiny detachments. As a result of the negative pressure, transudation from the hyperemic choroidal vessels ensues, which eventually leads to the ophthalmoscopically visible choroidal detachment. (63 illustrations, references.) F. Nelson.

Lijó Pavía, J., and Lachman, R. **Congenital aniridia; three cases.** *Rev. Oto-Neuro-Oft.*, 1945, v. 20, Aug., pp. 79-85.

Congenital aniridia may be complete or incomplete, unilateral or bilateral, and is associated with photophobia and diminished visual acuity. Pseudoptosis, microphthalmos, nystagmus, microcornea, corneal opacities, very deep anterior chamber, persistent pupillary membrane, ruptured suspensory ligament, lens opacities or subluxation, vitreous opacities, persistent hyaloid artery, optic atrophy, and fundus depigmentation, are occasionally associated with this congenital anomaly.

Three cases are reported. In the first there was bilateral total aniridia with nystagmus and lens changes; in the second there was total aniridia in one eye, almost total aniridia in the other, pseudoptosis, nystagmus, and excavation of the disc; in the third, a total unilateral aniridia was associated with pseudoptosis, nystagmus, and a pale fundus, while the fellow eye had a

normal iris, ectropion, and a senile cataract. (2 illustrations, references.)

Edward Saskin.

Rosen, Emanuel. **Rupture of choroid associated with cyst of vitreous.** *Brit. Jour. Ophth.*, 1945, v. 29, Sept., pp. 486-489.

Injury to the right cornea of a colored male resulted in reduction of vision to 20/200, which could not be improved by refraction. The pupil of the right eye was larger than that of the left and the temporal half of the pupil responded to light and accommodation more promptly than did the nasal half. Slitlamp examination showed a small superficial horizontal scar across the pupillary area of the cornea. The iris showed a definite break in its sphincteric portion at the 3-o'clock position.

The fundus showed a choroidal tear in the macular region running vertically and about three disc diameters in size. Below the disc was a cystic structure $2\frac{1}{2}$ times the size of the disc and shaped like an apple. This sphere seemed to be loosely suspended from a pedicle. As the patient looked upward, the mass would disappear, but upon his looking downward, it would settle back into its original position.

About a month after the first examination, the cyst was found to be ruptured, and the vitreous later showed some signs of clearing.

A similar case of vitreous cyst in a colored female is reported. There was rupture of the cyst with subsequent formation of a macular hole.

The author believes the tendency to excessive proliferation and encapsulation of tissue, as observed among Negroes, is responsible for traumatic cysts of the vitreous. (4 illustrations.)

Edna M. Reynolds.

Spyratos, S. The precursors of melanin as virulent nucleoproteins in the eye, with particular reference to sympathetic ophthalmia. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., pp. 605-614.

The pigment in all pigment cells consists of protein granules to which the melanin is firmly bound. In the earliest stages of pigment formation these granules are colorless and consist of undifferentiated protein. Later they are transformed into black melanin granules under the influence of a pyrocatechin derivative in the presence of an oxidative ferment which is found in the immature-protein granules. In the eye this transformation normally takes place only in a certain period of embryonic life. When the pigment genesis is complete, the melanoblasts become chromatophores and normally continue in this function for life. Under abnormal conditions, melanophores may react with degeneration and dissolution of the cells and with pathologic proliferation of pigmented epithelial cells. Atypical embryonic melanoblasts form, in which abundant immature atypical protein granules, the precursors of pigment, occur, not only within the cell itself but also in the surrounding tissue. The question arises whether these protein granules are able to interfere with the biologic balance of the melanophores in the healthy fellow eye, and eventually lead to the formation of the same immature protein bodies. The author found a direct relationship between these granules, on the one hand, and the epithelioid cells and infiltration nodules of sympathetic ophthalmia, on the other. Under pathologic conditions *in vivo* and in tissue culture *in vitro*, the pigment granules are engulfed by phagocytes as foreign bodies. The be-

havior of pigmented epithelial cells and of the chromatophores of the choroid is different. The latter settle around the blood vessels in a characteristic way. Under pathologic conditions they are able to invade blood vessels. Free pigment granules are then found not only in the lumen but also in the endothelium of the vessel. Pigment epithelial cells may pass the barrier of the lamina vitrea and proliferate in the uvea and even cover organized masses of exudate. In histologic preparations impregnation with silver makes mature pigment granules as well as their colorless precursors visible. With this staining method a direct relationship between free pigment granules and the epithelioid cells found in sympathetic ophthalmia could be established. The granules are found abundantly engulfed by the epithelioid cells. The author conducted numerous experiments with tissue cultures to clarify the reactions of the cells of the organism to free pigment granules. The pathogenic effect of the melanin granules and especially of the precursors of melanin in sympathetic ophthalmia seems to be firmly established. They act as virulent proteins like microbes or viruses. (6 photomicrographs, bibliography.)

GLAUCOMA AND OCULAR TENSION

Awerbach, M. L. Cyclodiathermy in secondary glaucoma. *Amer. Rev. Soviet Medicine*, 1945, v. 3, Oct., p. 35.

A general report of the results of 52 cyclodiathermy operations on 49 patients is presented. The author believes

that coagulation of the ciliary body is a safe procedure and reports satisfactory results. The procedure is simple and can be followed by other procedures when it proves ineffective.

Morris Kaplan.

Arruga, H. **Optico-ciliary neurotomy as a treatment for expulsive hemorrhage.** *Ophthalmologica*, 1943, v. 105, Feb., pp. 106-107.

A patient with painful absolute glaucoma refused enucleation. A retrobulbar injection of alcohol relieved the pain temporarily. A Lagrange operation with iridectomy was started, when an expulsive hemorrhage occurred. Immediate trephining of the sclera was ineffective. Optico-ciliary neurotomy was then performed. The hemorrhage ceased; the eyeball preserved its form; the pain did not recur.

Alice R. Deutsch.

Bhalerao, C. K. **Glaucoma.** *The Anti-septic*, 1945, v. 42, Dec., p. 706.

The author reviews glaucoma for the general practitioner of India. Several unusual ideas are presented. He believes that surgery should be done in acute congestive glaucoma if the tension remains high after two hours of medical treatment, and that in chronic glaucoma medical treatment is of no value.

Morris Kaplan.

Bonnet, P. **Congenital aniridia and chronic glaucoma.** *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 169.

Bonnet reports a case of bilateral chronic glaucoma, in which there was a total aniridia of the left eye. Although the glaucoma of the left eye manifested itself first and progressed to complete loss of vision, the glaucoma of the right eye was almost equally severe. There was no favorable response to

miotics. The author believes that there may have been a developmental anomaly in the right eye to account for the glaucoma. Phillips Thygeson.

Gallois, Jean. **Nicotinic acid in ophthalmology and the principle of minimal elective vasodilation.** *Arch. d'Opht.*, 1945, v. 5, No. 2, p. 197.

According to Gallois, the use of a vasodilator always carries a certain risk. Acetylcholine has frequently produced elevation in tension in mildly glaucomatous eyes. He has used nicotinic acid with satisfaction. It gives a vasodilation without modification of the arterial pressure and can be used either by mouth or by intramuscular or intravenous injection. He reports a series of 29 patients with chronic glaucoma in which the use of the drug resulted in significant lowering of the tension and increase in visual acuity and fields. In nine patients results were unfavorable. The favorable results were obtained in glaucoma at onset, glaucoma of slow evolution, and glaucoma with only slightly elevated tension. An individual oral dose of 30 mg. was usually satisfactory. General and local reactions could be expected within an hour. The treatment was given daily for three days of each week. Occasionally it was necessary to reduce the doses to 20 or even to 10 mg.

Marchesani, O. *Ophthalmomalacia* (essential hypotony). *Klin. M. f. Augenh.*, 1942, v. 108, Nov.-Dec., p. 692.

The author describes three cases of typical essential hypotony with linear opacities in the cornea. In a man, 18 years of age, whose right eye had been enucleated because of unbearable pain and progressive atrophy six months before, the left eye became similarly affected. The eye was inflamed and photophobic, and the cornea had gray subepithelial irregular linear opacities. The corneal parenchyma was clouded, and the tension was very low. During five weeks of hospitalization, improvement of all symptoms was observed; three weeks later there was a recurrence. Histologic examination of the right eye revealed pronounced thickening of the corneal stroma and epithelium at the site of the linear opacities. Iris and ciliary body were edematous. In the second patient, a man 33 years of age, a typical linear keratitis in the right eye was associated with hypotony and symptoms of a sympathetic paresis on the right side. He recovered fully without treatment and a recurrence four weeks later in the left eye healed within three weeks. The third patient, a man 44 years of age, was injured in a motorcycle accident. The right eye was destroyed completely, the skull and some other bones were fractured. There was right-sided Bell's palsy. The left eye had suffered contusion. The initial intraocular pressure was unmeasurably low, there was a temporal hemianopsia, and pallor of the disc. The visual acuity eventually improved to 5/15. To explain the pathogenesis of the ophthalmomalacia the author postulates a disturbance of the exchange of the intraocular fluid

which is opposite to that of primary glaucoma. In these patients capillary microscopy of the fingernail beds usually reveals a disturbance of the capillary circulation, and the blood pressure is low. (1 color plate, 4 photomicrographs, 2 capillary photomicrographs, bibliography.) F. Nelson.

Redslob, E., and Delbos, R. *Sympathetic ophthalmia without manifest exciting inflammation*. *Ophthalmologica*, 1943, v. 105, Feb., pp. 83-90.

An unusual sympathetic ophthalmia gives the opportunity to discuss Redslob's theory concerning the pathogenesis of this disease.

A left eye with a double traumatic perforation developed a severe purulent iridocyclitis immediately after the accident. The eyeball became pale, and there were signs of early shrinkage. No corneal precipitates were visible. An unexplained orbital pain remained. Three months later, a low-grade iridocyclitis with corneal precipitates developed in the uninjured eye and caused considerable impairment of vision. The injured eye was enucleated at once. A nonspecific inflammation was found in the neighborhood of the wound, and there was sympathizing ophthalmitis in the posterior part of the choroid.

To explain these findings the authors refer to Redslob's theory of the pathogenesis of sympathetic ophthalmia. The etiologic agent of the sympathetic ophthalmia is believed to invade the perforating wound with its enclosed uveal tissue. Here it causes a primary focus of inflammation. An inactive period follows during which the uvea becomes sensitized to uveal tissue. The sensitizing agent reaches the choroid through the short posterior ciliary arteries, and the iris and ciliary body

through the long posterior ciliary arteries.

In the present case the long posterior ciliary arteries were spared, and the iris and ciliary body were not affected; therefore, a clinical diagnosis in the injured eye was not possible. There were no characteristic changes in the anterior part, and the fundus could not be seen. The severe orbital neuralgia which disappeared after enucleation might be a suggestive diagnostic sign.

Alice R. Deutsch.

Reese, A. B. The iridencleisis operation for glaucoma. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 360-368.

The feeling prevails to some extent that it is not a sound surgical procedure to incarcerate iris tissue deliberately for the relief of glaucoma when on all other occasions an effort is made to prevent such an occurrence.

On Reese's service the operation has been performed on 110 eyes, during the past three years, and this report is based on the experience encountered in that series of consecutive operations.

An incarceration of prolapsed iris may be good or bad, depending on the manner in which it occurs. After an operation, especially a cataract extraction, an incarceration may lead to a filtering cicatrix or to secondary glaucoma. If the iris is incarcerated as a wick of tissue with the surfaces of the pigment epithelium together, it is more likely to produce a filtering cicatrix.

When an iridotaxis is done, the sphincter muscle pulls the pupillary border of the iris partly back into the anterior chamber. This leaves a pocket of iris which blocks the wound increasingly because of its progressive dilation by the aqueous. This can best be prevented by cutting the sphincter

muscle, extending the radial incision in the iris to the very periphery of the iris, and there leaving no portion of the root of the iris over the site of the coloboma.

The technique here described incorporates these factors.

A keratome section is made under a large conjunctival flap. The point of the keratome engages the conjunctiva at least 10 mm. from the limbus, and the conjunctiva is dragged down over the point of the keratome to the point of scleral puncture. Three-fourths the length of the keratome blade is introduced into the anterior chamber, and the conjunctival opening is enlarged on each side with a scissors. The operator withdraws the iris by grasping it at the pupillary margin. An assistant holds the iris on the opposite side, and in unison they withdraw the iris until an iridodialysis is just noted. Then a radial cut is made through the iris into the iridodialysis opening. The assistant releases the iris, and the operator then incarcerates each pillar into the corner of the wound with a minimum of manipulation. The conjunctiva is closed with interrupted silk sutures. Drops are not instilled.

The most important step in the operation is a correct incision. This should be made far back so that the point of the keratome enters the anterior chamber in or close to the chamber angle.

The operation is effective primarily because the wicks of iris produce a vicarious filtering sluiceway, but also because the iridodialysis frees the chamber angle over the coloboma area. This gives the effect of a basal iridectomy. When the iris is pulled up and out of the wound above, the iris below is stretched, which widens the angle and prevents the iris from blocking the

filtration angle. This widening of the angle below can be observed by gonioscopic examination.

Iridencleisis produces less drainage. It is therefore indicated when the maximal tension is less than 50 mm. Hg (Schiotz), and the basal pressure is 30 mm. Hg or less.

When one or more operative procedures have failed, the use of iridencleisis has not proved satisfactory.

When Reese advises surgery for glaucoma in an eye which still has normal vision and a normal field he prefers that there be not only an excellent chance of arresting the disease but that there is negligible danger of complications. This is definitely true of iridencleisis.

Sympathetic inflammation has not appeared in this series. He believes, however, that the incidence of sympathetic inflammation must be somewhat higher after iris-inclusion operations than after other intraocular operations.

The article is followed by valuable discussion. (Nine figures.)

R. W. Danielson.

Tartar, J. How do the hormones of the posterior lobe of the pituitary gland affect glaucoma? *Klin. M. f. Augenh.*, 1942, v. 108, Nov.-Dec., p. 737.

Recent investigations have shown that the regulation of the intraocular pressure depends partly upon the function of certain endocrine glands. Many different endocrine preparations, among them meropitan, which is an extract of the posterior lobe of the pituitary, have been used successfully to reduce the intraocular pressure in simple glaucoma. The author observed more than 100 cases of glaucoma, 45 of them simple glaucoma, 3 acute inflammatory glaucoma, 24 chronic inflammatory

glaucoma, 15 absolute glaucoma, 4 juvenile glaucoma, and 5 postoperative glaucoma. Some of them had not been treated with any miotics previously, in others there had been continuously high tension in spite of the use of miotics. He used pituisan, which contains all the hormones of the posterior lobe, oxytocin, and vasopressin. The extracts were administered either subconjunctivally or intramuscularly. Oxytocin and vasopressin appeared to be ineffective. In 24 cases decrease of the tension was obtained, in eight a very sudden drop. Absolute glaucoma, juvenile glaucoma, and acute inflammatory glaucoma did not respond to posterior-lobe extract. Simple and chronic inflammatory glaucoma responded best, but the response was usually of short duration and rarely permanent. When the glaucoma was probably a manifestation of an endocrine disturbance, results were most striking. (1 chart, bibliography.) F. Nelson.

Troncoso, M. U., Diathermy in glaucoma. *Amer. Jour. Ophth.*, 1946, v. 29, March, pp. 269-290. (18 figures, references.)

Weekers, Roger. Incomplete glaucoma. A contribution to the study of glaucoma without hypertension. *Ophthalmologica*, 1942, v. 104, Dec., pp. 316-331.

Changes in the intraocular vessels are responsible for the symptom complex called chronic idiopathic glaucoma, whose classical signs and symptoms—namely, hypertension, glaucomatous cupping, and the typical constriction of the visual fields—are caused by changes in the blood vessels of the uvea, optic nerve, and retina.

There are cases of glaucoma in

which there are a pathologic cupping and a characteristic constriction of the visual fields but normal ocular pressure. Wiekens refers to glaucoma without hypertension "incomplete glaucoma." Cases of optic trophy with excavation but without hypertension and without the typical defects in the fields he calls "monosymptomatic glaucoma."

Personal observations and cases from the literature are discussed. (4 figures, references.) Alice R. Deutsch.

CRYSTALLINE LENS

Albaugh, C. H. Congenital anomalies following maternal rubella. *Jour. Amer. Med. Assoc.*, 1945, v. 129, Nov. 10, p. 719.

Conclusions are drawn from 78 cases of maternal rubella during pregnancy, previously reported, to which the author adds nine. All of the babies whose mothers were infected with rubella during the first two months of pregnancy and one half of those whose mothers were infected during the third month had congenital anomalies. The commonest lesions were cataract, defects of the cardiac septum, patent ductus arteriosus, deaf-mutism, and microcephaly. It is suggested that all girls be exposed to rubella before maturity. An effective vaccine is desirable. The propriety of legal abortion should be discussed. Morris Kaplan.

Bonfioli, A. Sutures in the cataract operation. *Rev. Brasileira de Oft.*, 1945, v. 4, Dec., pp. 149-175.

The author describes and illustrates the sutures employed by various operators, and concludes by describing the special scleroconjunctival suture used in the ophthalmic clinic of the São

Geraldo Hospital of Belo Horizonte. He considers that cataract operation demands a sclerocorneal suture for safety and efficiency. (Numerous illustrations, bibliography.) W. H. Crisp.

Cole, H. N., Giffen, H. K., and others. Congenital cataracts in sisters. *Jour. Amer. Med. Assoc.*, 1945, v. 129, Nov. 10, p. 723.

Congenital ectodermal dysplasia in two sisters aged 10 and 22 months is described. These are unique in that all of the ectodermal tissue is involved. There was bilateral congenital cataract and severe internal strabismus.

Morris Kaplan.

Girardet, M. Another family with central pulverulent cataract. *Ophthalmologica*, 1943, v. 105, Jan., pp. 24-36.

The clinical appearance and the mode of transmission of a hereditary, central cataract in an afflicted family are discussed.

The cataract manifests itself as a central, punctate opacity which has slight morphologic variations so that four different groups can be distinguished.

1. A discoid opacity in the embryonic nucleus with a clear central interval as described by Poos.

2. A discoid, sharply outlined opacity in the embryonic nucleus with coarse punctate opacities in the central interval as described by Vogt.

3. A combination of the manifestations of 1 and 2.

4. Special atypical opacities which consist of a delicate circle superimposed on a dense, irregular Y.

When these malformations appear in their characteristic forms, similar to their ancestral genotype, they follow the law of dominant heredity. The atypical forms are not hereditary. It is

presumed that their appearance is a sign of a change in the transmitting gene. (5 figures, references.)

Alice R. Deutsch.

Hymes, Charles. Scleral flap incision with scleral sutures for the cataract operation. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 374-377.

In order to overcome all the handicaps of other types of sutures and at the same time to afford firm and exact apposition of the lips of the wound, the technique of the scleral-flap incision and scleral suture was devised. A description follows:

A small conjunctival flap of about 3 mm., is dissected over the upper half of the cornea to the limbus. The eyeball is fixed with a scleral pick, and the scleral flap is made by means of a scleral knife which is concave anteriorly, or by a Lundsgaard knife. The incision starts 1 to 1.5 mm. above the limbus, and the scleral knife is kept at a shallow level while the incision is made, in order to avoid cutting through the sclera, which at this place is 0.5 mm. thick. The knife is carried toward the limbus and stops short of opening the eyeball.

A fine black-silk suture on a sharp, curved atraumatic needle is passed through the conjunctival flap, the tip of the scleral flap, and the corresponding portion of the upper scleral lip and, finally, the edge of the bulbar conjunctiva, above. The loop is drawn aside to permit the making of the incision.

When the scleral flap is turned downward toward the cornea, an interval of 1.5 to 2.5 mm. is created between the two parts of the suture, the size depending on the height of the scleral flap. This leaves ample space for the cataract knife to pass without the risk of cutting the suture. For additional

accuracy, however, Hymes prefers to use the keratome and scissors in making the incision.

Should the anterior chamber be very shallow, as in a case of glaucoma combined with cataract, an ab externo incision may be made.

On completion of the extraction, the scleral suture is firmly tied, and two or more auxiliary conjunctival sutures are placed. (8 figures.) R. W. Danielson.

Irvine, R. S. Removal of the dislocated lens under a conjunctival pocket flap. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., p. 398.

Irvine has developed and used in 10 cases a technique emphasizing the following features: a vertical incision of the conjunctiva, about 13 mm. long, beginning 5 mm. from the limbus, at the 9-o'clock position in the left eye and at the 3-o'clock position in the right eye; wide separation of the conjunctiva over the upper half of the globe; opening of the anterior chamber, with a keratome incision, under the everted edge of the flap; completion of the section, with scissors, under the flap; extraction of the lens with the loop; depressing the sclera under the flap, and a water-tight closure of the incision.

Irvine has been surprised at the small loss of vitreous. His only explanation is that the positions of the conjunctival and corneal incisions do not coincide. R. W. Danielson.

RETINA AND VITREOUS

Bonnet, P., Chauvire, E., and Gallet, M. A case of methyl-alcohol poisoning with amelioration by stellate ganglion block. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 220.

The authors report the case of a man aged 54 years, who became suddenly blind following the imbibing of methyl alcohol. When first seen the patient had no light perception. The pupils were dilated and fixed to light but reacted to accommodation-convergence. There was edema of the nervehead and retina. The urine contained albumin which disappeared in 48 hours. Treatment consisted in (1) daily stellate ganglion blocks alternately on the right and left, (2) daily subcutaneous injections of strychnine, and (3) daily intravenous injections of acetylcholine and "bevitine." Light perception returned on the seventh day. Two days later vision was $1/6$ in the right eye and $1/100$ in the left, with improvement to $1/2$ and $1/15$, respectively, 48 hours later. The final visual acuity obtained was right $2/3$ and left $1/15$, with a normal visual field in the right eye but a large central scotoma in the left.

The authors call attention to the late appearance of spasm of the retinal vessels in this patient. They believe that the stellate ganglion blocks were of value in minimizing the vascular phenomena, which they consider a very important factor in methyl-alcohol intoxications. Phillips Thygeson.

Bonnet, P., Paufigue, L., and Bonamour, G. Detachment of the retina and tuberculosis. Military tubercles, periphlebitis, and retinal detachment. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 210.

The authors report the case of a man 58 years of age with a detachment of the upper temporal part of the retina of the left eye and multiple tubercular lesions widely scattered over the fundus. Visual acuity was $2/10$. Physical examination showed an old fibrous pulmonary tuberculosis. The retina

was reattached by diathermy coagulation.

They also report the case of a man 39 years of age with a retinal detachment of the right eye involving the entire lower half of the retina. Vision was reduced to $1/8$. The superior temporal vein showed a periphlebitis, and in this quadrant there were multiple foci of choroiditis with connective-tissue proliferation. Periphlebitis of the retinal veins was also noted in the left eye. General physical and radiologic examination revealed no evidence of pulmonary or other tuberculous lesions, but the authors consider that the ocular lesions were probably tuberculous in nature.

They stress the value of meticulous examination of the apparently normal eye in all cases of retinal detachment.

Phillips Thygeson.

Bonnet, P., and Paufigue, L. Thrombosis of the central retinal vein, or of its branches, due to syphilis. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 172.

The authors note that syphilitic involvement of the retinal veins is rare. They report four cases of thrombosis due to syphilis recognized by clinical and serologic signs and by therapeutic response.

The first patient, 60 years of age, had a typical thrombosis of the central retinal vein with edema, hemorrhages, and a vision of $3/10$. The Wassermann and Kahn reactions were strongly positive. Muthanol was used in treatment, with a progressive return of vision and a rapid diminution in the retinal signs. A return to a vision of $10/10$ was obtained without residual changes in the fundus.

The second patient, 51 years of age, had a thrombosis of the inferior retinal

veins. Blood tests for syphilis were positive. Specific treatment resulted in complete healing in three months.

The third observation was of a woman 32 years of age who had a thrombosis of the superior temporal vein of the right eye with a vision of 4/10. Specific treatment resulted in rapid improvement; four months later vision was normal and the fundus appeared normal.

The fourth patient, a man 46 years of age, showed the typical picture of thrombosis of the central vein, although his vision was still 10/10. He gave a history of syphilis discovered 10 years previously, treated regularly, and pronounced cured after seven years. The Wassermann and Kahn reactions were negative. Nevertheless specific treatment was started and improvement was slow but satisfactory.

The characteristics of syphilitic thrombosis are described by the authors after a review of the literature as consisting in (1) pronounced dilatation and tortuosity of the retinal veins, (2) striking response to specific treatment, (3) absence of arterial hypertension, and (4) lack of marked diminution in visual acuity.

Phillips Thygeson.

Espildora Luque, C. Recurrent retinal detachment. *Arch. Chilenos de Oft.*, 1945, v. 1, March-April, pp. 25-27.

In a man, aged 43 years, there was a persistent tendency to recurrence of the detachment in various parts of the upper segment of the retina, without any invasion of the macular region or of the lower half of the retina. Reappearance of the detachment occurred in a zone, already cauterized, which became reattached after a second intervention. The eye tolerated four opera-

tions without complication, in spite of the fact that the other eye was in a maximal condition of pthisis bulbi after a single operation for the same retinal condition. The amount of myopia in the eye whose upper sector had been so frequently and extensively cauterized underwent no change.

W. H. Crisp.

Freusberg, O. Fundus lesions in spotted typhus. Preliminary report. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., p. 621.

The author gives a preliminary report of fundus lesions in spotted typhus observed at the Russian war front. Abnormalities of the eyeground were found in 15 to 20 percent of all patients. He describes three characteristic cases. All had a more or less pronounced papilledema, retinal edema, and perivascular nodules. Considerably rarer were small choroidal lesions which left pigmented atrophic areas when healed. The fundus changes occurred during the period when the exanthem reached the highest point between the fifth and ninth day after onset of the disease. At the end of the third week fundus changes were usually not found, with the exception of the papilledema, which gradually disappeared during the period of convalescence. A complete report with histologic findings will appear later.

F. Nelson.

Lijó Pavia, J. Alterations of the hypophyseal region. Treatment with gonadotropin. *Rev. Oto-Neuro-Oft.* 1945, v. 20, June-July, pp. 53-61.

Three patients are presented in whom hypophyseal derangements were suspected following fundus and visual-field studies. All had a markedly di-

minished visual acuity and a contraction of the field which was usually irregularly concentric. Fundus studies revealed arterial narrowing, and a retinopathy characterized by atrophy of the inner layers of the retina, especially in the macular area. On the basis of the observations of several investigators and on roentgenograms of the sella turcica, the author ascribed these conditions to hypophyseal alterations. He prescribed sex hormones to restimulate the circulation, especially in the retinal arterioles and the choroidal vessels. Some improvement of visual acuity is reported. (7 retinographs, references.) Edward Saskin.

Paufique, L., and Bonamour, G. The prognosis of retinal-detachment operations in myopes. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 199.

In a series of 200 retinal detachments the authors observed 89 in myopic eyes. The right eye was involved slightly more frequently than the left, and detachment was slightly more frequent in myopic females than in myopic males. In most cases there was only one retinal tear, and this was frequently located in the upper temporal quadrant. Detachments in myopia greater than 10 diopters occurred almost exclusively before the age of 50 years; in eyes with a myopia of less than 10 diopters they usually occurred after 50 years of age.

Of the 89 patients nine were not treated, seven because of obvious contraindications such as thrombosis of the central vein and active chorioretinitis. In the 80 surgical operations the authors obtained 59 reattachments and had 21 failures. Six of the reattachments required reoperation because of recurrence.

Of the 21 failures, 10 were in indi-

viduals over 60 years of age. Vitreous hemorrhage occurred in four of these and in three there were gross tears with floating flaps which could not be obliterated at operation. In the other three no ocular reason for failure could be determined, but the patients were all suffering from severe arterial hypertension. Of the 11 failures in patients below the age of 60 years, two had myopia of more than 20 diopters with total detachments complicated by multiple tears; two were in patients with severe posttraumatic detachment, one complicated by subluxation of the lens and the other by vitreous hemorrhage; two were in individuals over 70 years of age; one was in an old detachment without visible tears; and one was in a patient with total detachment and numerous tears near the ora serrata extending over three-fourths of the retinal circumference. Finally, there were three cases which were considered clinically to have a favorable prognosis but in which healing did not follow.

In the 59 patients with reattachment there were only three in which a vision of less than 1/10 was obtained. Six had between 1/10 and 2/10, 30 had between 2/10 and 5/10, and there were 10 with an acuity above 5/10. The authors conclude that they would have had an operative success of 93 percent if the figures were revised to eliminate the truly inoperable and the aged myopic eyes in which detachment could be considered more arteriosclerotic than myopic. Phillips Thygeson.

Paufique, L., and Bonamour, G. Thrombosis of the central retinal artery in a child. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 222.

A child nine years of age suddenly lost the vision of the right eye. There were no prodromal symptoms and no

irritative signs or pain in the eye. The next day ophthalmoscopic examination revealed the characteristic picture of thrombosis of the central retinal artery. Paracentesis of the anterior chamber was performed immediately and systemic treatment with acetylcholine and "muthanol" instituted, but there was only insignificant improvement in the fundus in the next few days. General physical examination was negative. The Bordet-Wassermann reaction was negative. The Kahn and the Meinecke reactions were questionably positive. The father, however, had been treated some time previously for a syphilitic gumma, and on this basis the authors concluded that the lesion in the child was probably due to congenital syphilis. They stress the rarity of thrombosis of the central artery in children. Phillips Thygeson.

Paufique, L., and Bonamour, G. Prognosis of operations for senile retinal detachments. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 226.

The authors report statistics on 57 senile detachments. They define senile detachments as those occurring in the aged in the absence of marked refractive error, traumatism, tumor, secondary-membrane formation, or tuberculous or syphilitic lesions. About 30 per cent of detachments fell into this group. They showed no special clinical characteristics except frequent sclerotic changes in the retinal vessels. Of the 57 detachments, 46 were treated surgically, with success in 22. Of the 24 failures, 8 had initial reattachment followed by recurrence during the first three months of observation. Probable causes of failure included giant tears, massive postoperative vitreous hemorrhage, and multiple tears. In the 22 successes there were three

patients with a visual acuity between $2/3$ and 1, 13 with acuity between $1/4$ and $1/2$, and 6 with acuities between $1/10$ and $1/6$. The prognosis is definitely poorer for senile detachment than for other forms, and caution is recommended in advising operation in the aged who have one normal eye.

Phillips Thygeson.

Reca, A. B. Coats's exudative retinitis. *Anal. Argent. Oft.*, 1945, v. 6, Jan.-Feb.-March, pp. 1-5.

The condition is characterized by whitish masses at the posterior pole of the retina, occasionally including the disc, with or without vascular changes. Associated miliary aneurysms have been observed. The disease usually progresses with complications, detached retina, secondary cataract, iridocyclitis, and glaucoma. The latter occasionally necessitates enucleation. Tuberculosis, syphilis, and childhood diseases have been discussed as etiologic factors.

A 17-year-old girl is described, who, in the left eye, had typical massive exudative retinitis which was temporal to the disc and involved the macular area. All laboratory tests were negative. A differential diagnosis must exclude hereditary macular degeneration, disciform degeneration of the macula, retinitis circinata, tuberculous exudative retinitis, retinal degeneration with miliary aneurysms, tumors, and von Hippel's disease. (1 illustration.)

Edward Saskin.

Rodin, F. H. Hypertensive retinopathy associated with adrenal medullary tumor (pheochromocytoma). *Arch. Opth.*, 1945, v. 34, Nov.-Dec., pp. 402-407.

Pheochromocytoma is a rare form of chromaffin tumor, characterized by

a train of hypertensive symptoms, including definite ocular changes.

Epinephrine or an epinephrine-like pressor substance is contained in the cells of this tumor. Large amounts of this substance freed into the blood stream cause vasoconstriction, elevate blood pressure, and stimulate the sympathetic nervous system, producing paroxysms of hypertension. In the eye, changes are typical of hypertensive retinopathy.

Extensive changes in the retinas, characterized by changes in the retinal vessels, hemorrhages, and formation of exudate, were observed in a patient with an adrenal medullary tumor (pheochromocytoma). After removal of the tumor the ocular phenomena disappeared, as illustrated by serial photographs. There is no definite explanation of the mechanism by which the retinal changes are produced.

R. W. Danielson.

Vetter, J. Unilateral thrombosis of the central vein as a result of chronic chromate poisoning. *Klin. M. f. Augenh.* 1942, v. 108, Nov.-Dec., p. 720.

Chromic acid and its salts are poisonous. Workers in chromium-plating factories are constantly exposed to the fumes and dust of chromium compounds. Chronic rhinitis with destruction of the nasal mucous membrane and perforations of the nasal septum are the most characteristic result. Chronic bronchitis and bronchial carcinoma have been observed. Conjunctivitis and keratitis, and, less frequently, ulcers of the lids are seen. Fundus changes have been reported rarely. Vetter describes a man, 36 years of age, who had been employed in a chromium-plating factory for 16 years, who showed superficial and deep corneal opacities with regional vasculari-

zation in the left eye and a typical defect of the nasal septum. He had several recurrences in both eyes over a period of years. In January, 1942, the patient returned with a typical thrombosis of the left central retinal vein with central scotoma and some loss of vision. Rapid and almost complete recovery followed when the patient was removed from exposure to chromates. (Bibliography.) F. Nelson.

OPTIC NERVE AND TOXIC AMBLYOPIAS

Ostow, Mortimer. The significance of the depth of the physiologic cup of the optic disc for mental ability. *Jour. Nervous and Mental Disease*, 1945, v. 102, Dec., p. 571.

The author found a correlation between the depth of a physiologic excavation of the disc and intelligence. Four hundred and eighty persons, patients in mental hospital and non-psychotic prisoners, were examined. Among persons of high intelligence the greater number had a deep excavation of the disc, whereas flat discs predominated in individuals of low intelligence.

No relation was found to exist between disc cupping and the type of mental abnormality.

The author suggests that the physiologic excavation of the disc may be a manifestation either of an advanced stage of maturation of the structures of the central nervous system or of a superior type of physical growth. Superior intelligence might be another manifestation of the same process.

R. Grunfeld.

Tupin, M. A case of posthemorrhagic amblyopia. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 246.

A case of amblyopia in a man aged 37 years, suffering from hemorrhage secondary to a gastric ulcer, is reported. Vision $2\frac{1}{2}$ months after the hemorrhage was O.D. 5/10 in the right eye and perception of fingers at 10 cm. in the left. Ophthalmoscopic examination revealed optic atrophy, and the visual field of the better eye was limited to the central area plus a superior sector. The patient's general physical condition was good at the time. Post-hemorrhagic amblyopia is fairly common; reports of 250 cases have been reported up to 1935. In 87 percent of the reported cases the amblyopia was bilateral and the onset was most frequently between the third and sixteenth days; in about 40 percent of the reported cases some vision was recovered. Ischemia alone is insufficient to explain the pathogenesis of the amblyopia, since it occurs in only a small percentage of patients with severe hemorrhage. There is a widespread belief that some disturbance in the general health is necessary for the production of amblyopia. The subject of this report was a prisoner of war for $3\frac{1}{2}$ years and consequently suffered from a dietary deficiency.

Phillips Thygeson.

Yaskin, H. E., and Alpers, B. J. Foster Kennedy syndrome with post-traumatic arachnoiditis of optic chiasm and base of frontal lobes. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 399-401.

The syndrome of atrophy of the optic nerve of one eye and papilledema in the other eye has come to be regarded as evidence of a tumor lying at the base of the frontal lobe. This relation was first pointed out by Paton (1909) and was further elaborated by Foster Kennedy (1911). Recent studies

have indicated that the syndrome may be found at times in association with arteriosclerosis of the internal carotid arteries, which compress the optic nerves and chiasm. The Foster Kennedy syndrome may thus be found in conjunction with disorders other than tumor and the conditions under which the syndrome may occur have been studied. Experience with a recent case indicates that it may develop also as a result of arachnoiditis in the region of the optic nerves and optic chiasm. This case is reported in detail.

R. W. Danielson.

EYEBALL AND ORBIT

Babel, Jean. A histologic study of ocular rheumatism. *Ophthalmologica*, 1942, v. 104, Nov., pp. 243-253.

Babel reports the clinical and pathologic findings in a case of a severe recurrent sclerotenonitis. He emphasizes the similarity between the histologic findings in the eye and in the other organs. The eye which he studied histologically was examined in a stage of regression of the primary disease, whereas the eyes previously described were all in the latest stage of the disease and were enucleated because of absolute glaucoma.

A man, 35 years of age, who had suffered from a recurrent rheumatic sclerotenonitis died of cardiac insufficiency. Pathologic studies of the right eyeball and the other organs is reported in detail. There was extensive dilatation of the veins and capillaries and a dense perivascular infiltration which consisted of lymphocytes, plasma cells, large, bright cells with basophile granules (similar to Aschoff's cells), and an occasional multinucleated giant cell. Those changes

were seen in the sclera, Tenon's capsule, the uvea, and the extraocular muscles. In the periorbital tissue there were similar aggregations of cells about the ciliary nerves. There also were typical rheumatic nodules in the extraocular muscles, where they formed a real rheumatic myositis. There was vascular sclerosis in the retina, and Tenon's space was obliterated. The optic nerve was normal despite the dense peribulbar infiltration. The cornea, lens, and vitreous were normal. Similar but less typical nodules were found in the myocardium, and in the synovial membranes. (References, 5 figures.)

Alice R. Deutsch.

Mattos, W. B. Palpebroconjunctival autoplasty. *Arquivos Brasileiros de Oft.*, 1945, v. 8, nos. 4 and 5, pp. 103-109.

The author briefly summarizes his own technique, as follows: He first incises horizontally the conjunctiva lining the cavity, parallel to the lid margins, from one canthus to the other. He then dissects back the conjunctiva to form two flaps, upper and lower. Three U-shaped sutures are passed in each conjunctival flap, coming out along the superior tarsal border in the skin of the lids. These are tied over a roll of gauze. In this way the loose conjunctiva will cover the posterior surface of both lids, leaving in the depth of the orbit a large area which is to be covered with the graft. Including all the layers of the skin, and of a size and form capable of covering all the denuded orbital area, a pedunculated flap is cut from the temporal region, the tissues are buttonholed a little outside and below the external canthus, at the orbital margin, and the flap is introduced through the button-

hole, its tip being tied at the caruncle to maintain proper position. The skin is sutured in the temporal region. The angles formed by the grafted skin and by the conjunctiva transplanted under the lids form the upper and lower cul-de-sacs. After six days all the sutures are removed, and the transplanted skin within the buttonhole is strongly curetted to avoid formation of a fistula as the result of nonresection of the pedicle. (8 illustrations, 4 in color.)

EYELIDS AND LACRIMAL APPARATUS

Balod, K. An improvised dacryocystorhinostomy needle. *Klin. M. f. Augenh.*, 1942, v. 108, Sept.-Oct., p. 626.

Since it is not always possible to obtain special instruments during war time, Balod improvised a needle for dacryocystorhinostomy by bending the tip of a hypodermic needle to form a hook of desired size and angle after heating it in an alcohol flame. To obtain a suitable eye, the hook was filed transversely near the tip until a hole of sufficient size was obtained to admit the suture. The finished needle was attached to an ordinary syringe that served as a handle. (1 illustration.)

Hall, Arthur. The origin and purposes of blinking. *Brit. Jour. Ophth.*, 1945, v. 29, Sept., pp. 445-467.

The work reported is the result of an inquiry undertaken to find out to what extent the rate of blinking is reduced in the patient with chronic encephalitis.

The average rate of blinks per minute by patients with chronic encephalitis when in conversation was less than half that of normal subjects; yet when reading aloud, the rate of blinking was practically the same in the two groups.

Most of the blinking which occurs in daily life is in no way connected with the efficient action or protection of the eyes themselves but plays a part in the preservation of the organism as a whole. It is so brief that it does not interfere with vision and one is not aware of its occurrence. It varies in frequency and purpose.

A review of blinking in other vertebrates, which is indistinguishable from that in man, is given. Two involuntary unconditioned reflexes are inherited by all animals. These reflexes are opposed and cannot be in action at the same time. There are two distinct and opposed cortical ocular reflexes: one is excited by extramacular stimuli and effects movements of the eyes; the other is of macular origin and holds an object in central fixation. The extramacular reflex is more primitive in origin and of vital importance in self-preservation. The rate of blinking is much higher in the herbivora than in the carnivora. The fact that the blinking rate is higher in the "hunted" animal than in the "hunting" animal suggests that its purpose is connected with the self-preservation reflex.

Blinking in the arboreal primates is much higher than that in the lower animals, presumably due to interest in their surroundings, yet the primitive blinking of the self-preservation reflex in association with the other sense organs still remains exactly as in the lower animals.

In man, the rate of blinking is similar to that in the arboreal primates. The fixation-reflex constantly changing

in direction is essential, but the extramacular reflex for purposes of self-preservation is still present in its primitive form, and at any moment, when danger threatens, fixation is shut off by a blink and the eyes assume control of the body's activities in coöperation with the other sense organs.

Even in the congenitally blind in whom the act of fixation has never taken place, the eyelids blink when a threatening sound occurs. (6 figures, references.) Edna M. Reynolds.

Llanos, N. G. Dacryocystorhinotomy. *Rev. Oto-Neuro-Oft.*, 1945, v. 20, June-July, pp. 69-70.

Various procedures are discussed. The author favors that of Donato Valle, which he does not describe. He dislikes the hammer and chisel method of trepanning the maxilla and ethmoid. In suturing the mucosa of the sac to that of the nose he uses 000 catgut on Dechamps needles. Edward Saskin.

Pereira, R. F., and Tolosa, E. C. Dacryosinusitis simulating dacryocanalculitis. *La Semana Méd.*, 1945, v. 52, Dec. 6, pp. 893-896.

A man aged 40 years had chronic suppuration of the conjunctival cavity of the right eye, arising from the upper lacrimal canaliculus. Catheterization of the canaliculus demonstrated, under radiographic control, the existence of a dacryoethmoidal fistula, and rhinologic examination revealed a sinusitis of the ethmoids and of the maxillary of the right side. Surgical treatment of these conditions resulted in complete disappearance of the suppuration and spontaneous closure of the fistula. (References.) W. H. Crisp.
